Abstract

The study of the strong-field multiphoton processes is a subject of much current significance in physics and chemistry. Recent progress of laser technology has triggered a burst of attosecond science where the electron dynamics plays a vital role in underlying physics. The nonlinear strong-field phenomena, such as multiphoton ionization, multiphoton resonance, high-order harmonic generation, etc, are beyond the perturbative regime and demand novel theoretical approaches for better understanding. This dissertation aims at developing new theoretical and computational methods with innovative spatial and temporal treatments, and delivering comprehensive studies of strong-field multiphoton processes explored by the proposed methods.

The time-dependent Voronoi-cell finite difference method is a new grid-based method for electronic structure and dynamics calculations of polyatomic molecules. The spatial part is accurately treated by the Voronoi-cell finite difference method on multicenter molecular grids, featuring high adaptivity and simplicity. The temporal part is solved by the split-operator time propagation technique, allowing accurate and efficient non-perturbative treatment of electronic dynamics in strong fields. The method is applied to self-interaction-free time-dependent density-functional calculations to probe multiphoton pro-
cesses of polyatomic molecules in intense ultrashort laser fields with arbitrary field–molecule orientation, highlighting the importance of multielectron effects.

The generalized Floquet theory is extended for the investigations of an atom in intense frequency-comb laser fields and a qubit system driven by intense oscillating fields. For the frequency-comb laser generated by a temporal train of pulses, the many-mode Floquet theory is extended to treat the interaction of an atom and a series of comb frequencies, demonstrating coherent control of simultaneous multiphoton resonance processes. For the strongly driven qubit, the Floquet theory is extended and its analytic solution is derived to explore multiphoton quantum interference in the superconducting flux qubit.
Acknowledgments

First of all, I would like to express my sincere gratitude to my advisor, Prof. Shih-I Chu, for giving me the opportunity to work with him and for his constant support, encouragement, guidance, and inspiration. His enthusiasm for science and beyond will be always in my memory. To me, he is not only a role model as the great scholar but also the great mentor in many aspects.

Also I would like to thank my committee members, Prof. Thomas Cravens, Prof. Siyuan Han, Prof. Peter Hierl, Prof. Weizhang Huang, and Prof. Krzysztof Kuczera for their suggestions and thoughtful review on this work.

My special thanks go to Dr. N. Sukumar for his kind assistance about the Voronoi-cell finite difference method, Prof. Siyuan Han for invaluable discussions about the Floquet-qubit project, and Dr. Domagoj Pavičić and Dr. Wen Li for allowance to use their experimental data with useful discussions.

I am grateful to all Prof. Chu’s former and current group members. Especially I am indebted to Dr. Dmitry Telnov, aka Dima, and Dr. Zhongyuan Zhou for insightful explanations and fruitful discussions. It is my pleasure to thank Dr. Juan Carrera and Dr. John Heslar for making close friendship. Also I am thankful to Xiaoning Li and Jing Guo as good colleagues. I greatly appreciate all supports from Chemistry Department at University of Kansas. I wish to
thank all group members I have met at National Taiwan University. Although it was a short visit, I never forget the warm and friendly atmosphere from them.

With all my respects, I would like to thank my parents for their endless support and love. With all my hearts, I wish to thank my wife, Huijong, and my dear daughter, Hanna, for sharing love with me and discovering the happiness in my life.
Chapter 1

Introduction

The light–matter interaction is one of fundamentals in physics and chemistry. Light (i.e., the electromagnetic field) is a versatile tool to initiate, probe, and control physical and chemical processes. When the field strength is strong enough to ionize atoms and molecules, a number of novel strong-field phenomena [1, 2] come into view enlarging our insights in atomic, molecular, and chemical physics, and the electronic dynamics is a key ingredient to understand their underlying physics. The emergence of laser in science and technology opened new ways to study rich physics of the strong-field–atom and strong-field–molecule interactions. At the same time, the frequency-comb laser [3], which consists of a series of spectral lines, has revolutionarily impacted on high-precision spectroscopy and ultrafast science. The strong-field–atom interaction is ubiquitous in science. For example, strong-field multiphoton dynamics in artificial atoms can manipulate the qubit states for quantum computing [4].

The state-of-the-art advances of laser techniques lead to a birth of attosecond science [5, 6, 7]. In the attosecond (=10^{-18} sec.) timescale, we are able to achieve real-time observation and steering of the motion of electrons in atoms, molecules, and materials [7, 8], which might be one of ultimate goals most scien-
tists have dreamed of. Recent progresses of attosecond physics include attosecond pulse generation [9, 10, 11, 12], attosecond time-resolved spectroscopy [13], control of electron wave packets [14, 15, 16], probing of nuclear dynamics [17, 18] and electronic dynamics [19, 20], laser-induced electron diffraction [21, 22], lightwave electronics [23], electronic dynamics in chemical and biological phenomena [24], tomographic imaging of molecular orbitals [25, 26], and so on. Also exploration of the attosecond electronic dynamics in the strong-field regime, which cannot be examined in other ways, has attracted much interest theoretically and experimentally [27].

In this dissertation, we focus on theoretical exploration of the strong-field multiphoton processes with novel theoretical and computational approaches in space and time. The scope of the dissertation ranges from artificial atoms to polyatomic molecules, and from a continuous wave to the frequency-comb laser and ultrashort pulsed laser. We develop a new time-dependent Voronoi-cell finite difference method based on highly adaptive spatial discretization designed for polyatomic molecules. Also we extend the generalized Floquet formalism [28] for exact temporal treatments to study the interaction of quantum systems with frequency-comb laser fields and to analyze the strongly driven qubit system.

When the field strength is comparable to or exceeds to the Coulomb field experienced by outer-shell electrons in atoms, it is called a strong field\(^1\), corresponding to the intensity of around \(10^{15} \text{ W/cm}^2\) [2]. To help us imagine how strong it is, let us consider all energies from the Sun into the Earth as

\(^1\)Note that some authors distinguish between “strong” and “super-strong”, as the latter is equally called “intense” [29]. In this dissertation, however, we shall use both “strong” and “intense” as the same meaning, covering the intermediate regime (\(10^{13}–10^{15} \text{ W/cm}^2\)) and strong-field regime (\(10^{15}–10^{18} \text{ W/cm}^2\)) according to Ref. [2]
follows. Total solar insolation received at the Earth’s surface is about \(1.75 \times 10^{17}\) Watts [30]. If all solar energies on the Earth’s surface are concentrated into only \(5 \times 5\) inches\(^2\), then its intensity becomes about \(1.1 \times 10^{15}\) W/cm\(^2\), which is corresponding to the intensity of the strong laser field used in laboratory. In this dissertation, we shall cover the laser intensities from \(5 \times 10^{13}\) W/cm\(^2\) to \(2.5 \times 10^{15}\) W/cm\(^2\).

There are many of nonlinear optical phenomena in the strong-field regime, such as multiphoton excitation (MPE) [31], ionization (MPI) [32], and dissociation (MPD) [33], above-threshold ionization (ATI) [34, 35] and dissociation (ATD) [36, 37], multiple high-order harmonic generation (HHG) [38, 39, 40, 41], Coulomb explosion (CE) [42, 43], chemical bond softening and hardening [44], coherent control of chemical and physical processes [45, 46], etc. These novel processes are far from satisfactory when described by the traditional perturbative approaches. For a theoretical aspect, it demands a non-perturbative treatment to understand these strong-field phenomena.

To capture electronic structure and dynamics inside the strong-field processes, one needs to solve the non-relativistic time-dependent Schrödinger equation (TDSE) including the light–matter interaction [47],

\[
i\hbar \frac{\partial}{\partial t} \Psi(R, t) = H(R, t) \Psi(R, t).
\]

In fact, the whole of this dissertation is devoted to describe how to solve TDSE and what to do with TDSE solutions. Theoretical and computational challenges to solve TDSE for the molecular strong-field processes are categorized [48] as follows: i) many-electron quantum system, ii) spatial treatment for polyatomic molecules, and iii) temporal treatment in the non-perturbative way.
To address the first issue, we employ density-functional theory (DFT) and time-dependent density-functional theory (TDDFT) [49], which transforms an $N$-particle problem into an one-particle problem including all multielectron effects through the exchange and correlation functionals. It is worthwhile to note that conventional DFT methods are not applicable for accurate electronic structures and time-dependent problems due to spurious self-interaction energy and improper asymptotic behavior of the long-range potential. Therefore we implement self-interaction-free DFT and TDDFT with the proper long-range potential for electronic structure and dynamics calculations of polyatomic molecules.

Even for the one-electron problem in the 3-dimensional (3D) space, it is not trivial to obtain an accurate numerical solution because of the notorious Coulomb singularity between an electron and nuclei. To advance the spatial treatment for the Coulomb potential in 3D, Professor Chu’s group has pioneered the generalized pseudospectral (GPS) method and time-dependent pseudospectral (TDGPS) method on optimal nonuniform grids for atoms and diatomic molecules [41, 50]. To answer the second issue of the spatial treatment for polyatomic molecules, we develop the Voronoi-cell finite difference (VFD) method with the help of geometrical adaptivity of the Voronoi diagram. The VFD method offers very simple numerical expressions on very complicated spatial problems. The spatial part of TDSE for polyatomic molecules is accurately solved by VFD on highly adaptive multicenter molecular grids. This VFD method combined with self-interaction-free DFT formula attains accurate electronic structure calculations for polyatomic molecules.

Regarding the third issue, there are two approaches to treat the temporal part of TDSE in the non-perturbative way. The first one is the time propagation method where the time-dependent wavefunction is directly propagated
under time-dependent Hamiltonian including the light–matter interaction and time-dependent multielectron responses of the wavefunctions (through TDDFT formula). We integrate the VFD method and the split-operator time propagation technique into the time-dependent Voronoi-cell finite difference (TDVFD) method. By means of TDVFD, we can perform TDDFT calculations for probing strong-field multiphoton processes in many-electron polyatomic molecules for the first time. Since a full 3D calculation for polyatomic molecules has been formidable within traditional numerical methods, most of strong-field studies have been based on a simple model. On the contrary, the proposed method allows for detailed studies of attosecond electronic dynamics including multielectron responses. We explore strong-field phenomena such as multiphoton ionization (MPI), photoelectron angular distribution (PAD), and high-order harmonic generation (HHG) for small polyatomic molecules, emphasizing multielectron responses in multiple orbital dynamics.

The second approach for the temporal treatment is to transform the time-dependent problem into a time-independent problem in the framework of the generalized Floquet formalism [28]. In this approach, we can obtain an exact solution of the time-dependent problem with an illuminating physical picture. The generalized Floquet theory is extended to two physical problems of much current interests: the frequency-comb laser, which consists of a series of equal-spacing frequencies, and the qubit (quantum bit), which is a unit of quantum information. To handle a train of pulses generating the comb structure in the frequency domain, we extend the many-mode Floquet theory for the interaction of an artificial two-level system with a series of comb frequencies and discuss coherent control of simultaneous multiphoton resonance processes and HHG enhancement by tuning the carrier-envelope phase shift. We also extend
the Floquet theory for the exploration of multiphoton quantum interference in a superconducting flux qubit driven by intense oscillating fields and devise an analytic solution for multiphoton dynamics in the strongly driven qubit.

This dissertation is organized as follows. In Chapter 2, we introduce a new VFD method for solving the Schrödinger, Kohn–Sham, and Poisson equations for electronic structures of polyatomic molecules [51]. The high-order VFD method is also proposed with open prospects at the end of this chapter. In Chapter 3, we develop a new TDVFD method for an accurate and efficient solution of self-interaction-free TDDFT for polyatomic molecules [52]. We present detailed studies for orientation-dependent MPI of N₂ and H₂O [52] and MPI and PAD of aligned CO₂ [53], as well as HHG of aligned CO₂. In Chapter 4, MMFT is extended for intense frequency-comb laser fields to investigate coherent control of multiphoton resonance dynamics and HHG enhancement for a two-level system [54]. Note that HHG driven by intense frequency-comb laser retains the comb structure for each harmonic [55]. In Chapter 5, we extend the Floquet theory for the strongly driven qubit system and explore multiphoton quantum interference by numerical and analytical studies [56]. It is concluded with a summary of present works in Chapter 6.

For publications, the author has played an active role to prepare Refs. [51, 52, 53, 54, 56] and a partial role for Ref. [55]. He has developed all computer programs to present numerical results in all above publications.

The proposed novel spatial and temporal treatments to solve TDSE will be able to pave the way toward detailed theoretical studies of attosecond electronic dynamics in polyatomic molecules including multielectron effects, and an universal method for artificial atoms and realistic systems in any shaped intense fields.
Chapter 2

Development of a new grid-based method for the electronic structure calculations of polyatomic molecules: Voronoi-cell finite difference method

We introduce a new numerical grid-based method in three-dimensional (3D) real-space to investigate the electronic structure of polyatomic molecules. The Voronoi-cell finite difference (VFD) method is developed to accurately and efficiently solve the Schrödinger equation on unstructured grids with the help of geometrical adaptivity of the Voronoi cells and their natural neighbors. The feature of unstructured grids enables us to choose any intuitive pictures for an optimal molecular grid system, so we design highly adaptive multicenter molecular grids which consist of spherical atomic grids located at nuclear positions. In this way, we can circumvent the multicenter Coulomb singularity in all-electron calculations of polyatomic molecules. This new VFD method augmented by multicenter molecular grids is applicable to solve the Schrödinger /
Kohn–Sham equation and the Poisson equation with the all-electron Coulomb potentials, regardless of the coordinate system and the molecular symmetry. For numerical examples, we assess accuracy of the VFD method for electronic structures of one-electron polyatomic systems, and apply the method to the density-functional theory (DFT) for many-electron polyatomic molecules. Furthermore, the VFD method is advantageously suitable for time-dependent calculations because it does not demand massive integration to construct the time-dependent Hamiltonian. Extension to time-dependent VFD method and its many applications will be described in details in Chapter 3.

2.1 Grid-based methods for electronic structure and dynamics calculations

The structure and motion of electrons in molecules are the most fundamental topics in atomic and molecular physics and quantum chemistry. The basis set expansion method based on linear combination of atomic orbitals (LCAO) [57] is one of the most conventional methods in quantum chemistry to investigate molecular electronic structures. Despite its wide spread of usage, there have been several drawbacks in the LCAO scheme, such as massive integrals, slow convergence for basis sizes, basis set superposition error [58], and linear dependence problems [59]. In particular, the basis set expansion method based on localized atomic orbitals hinders from exploring strong-field electronic dynamics which inevitably cover long-range motions of the electrons, even though there have been several attempts to use the basis set expansion in strong-field time-dependent calculations [60]. On the opposite side, the numerical grid-based method to solve the Hamiltonian directly represented in real-space grids [61]
has been chosen for describing electronic dynamics, widely in atomic and molecular physics. It is relatively easy for the grid method to be extended to excited/continuum states in electronic dynamics by including long-range grid points, but it requires local refinement of grids to accurately compute even electronic structures of polyatomic molecules, which are prerequisite for electronic dynamics.

From the numerical aspect, the multicenter Coulomb singularity is a key bottleneck for the accurate treatment of electronic structure and dynamics in polyatomic molecules. The Coulomb potential \(=1/r\) in the all-electron Hamiltonian of atoms and molecules incorporates cusps at nuclear positions in electronic wavefunctions, which is called Coulomb singularity [62] that significantly affects accuracy of electronic bound states. The realistic Coulomb potential also influences highly-excited and continuum electrons due to its long-range behavior. The importance of Coulomb effect in the continuum states has been explicitly discussed for strong-field ionization process [63] and high-order harmonic generation [64, 65].

To achieve both the short- and long-range manners of the realistic Coulomb potential, Professor Chu’s group [41, 49, 50, 66, 67] has developed the generalized pseudospectral (GPS) method and time-dependent generalized pseudospectral (TDGPS) method on an optimal nonuniform grid system which has denser grid points near the nuclear positions and sparser grid points away from the nuclei. For atomic systems with the spherical coordinates [41] and diatomic systems with the prolate spheroidal coordinates [50, 66, 67], the GPS method has brought in machine accuracy to electronic structure calculations and the TDGPS method has achieved a remarkable success in calculations of strong-
field electronic dynamics such as multiphoton ionization and high-order harmonic generation (for examples, see Ref. [49] and references therein).

As the number of nuclei goes beyond uniaxial and diatomic systems, however, it is not trivial to employ a coordinate system suitable for arbitrary geometries of polyatomic molecules. From this viewpoint, numerical methods on unstructured grids [68], which have no fixed number for connectivity among grids, become much attractive for calculations of polyatomic molecules. On unstructured grids we can construct highly adaptive nonuniform molecular grids with variable resolutions around nuclear positions, regardless of the coordinate system and the molecular symmetry.

For an optimal molecular grid system, it is natural to consider that molecular grids consist of a combination of spherical atomic grids centered at nuclear positions, which can be called multicenter molecular grids. This intuitive idea was introduced and implemented by Becke [69] and Dickson and Becke [70] for basis-set-free DFT calculations. Becke’s procedure was based on multicenter numerical integration [71, 72] and solved the Schrödinger equation by means of the single-center decomposition with the spherically-averaged approximation [73], rather than a direct solution on molecular grids. The direct solution on such a multicenter molecular grid distribution is most desirable but not trivial with conventional numerical grid-based methods.

To directly solve the Schrödinger equation or, more generally, the partial differential equations (PDE) on unstructured grids (e.g., multicenter molecular grids), one can imagine the Voronoi diagram [74, 75, 76]. Because the Voronoi diagram is geometrically attractive and versatile, there have been tremendous applications in various areas of science and engineering over one century [77, 78]. However, a PDE solver exploiting geometrical advantages of the Voronoi
diagram has not been considered until relatively recent years. In geophysics and solid mechanics, the natural element method (NEM) [79] and the natural neighbor Galerkin method (NNGM) [80, 81] have been developed to realize PDE solutions on unstructured grids with the help of Voronoi diagram. More recently, Sukumar [82] and Sukumar and Bolander [83] proposed the discrete Laplacian operator for numerical solutions of the Poisson equation on unstructured grids based on the finite difference scheme with Voronoi cells and natural neighbors, and named it the Voronoi-cell finite difference (VFD) method. Because there is no restriction on the location of grid points, the VFD method with arbitrary unstructured grids is regarded as a meshfree (or meshless) method, which is of current interest in computer modeling and simulation in engineering applications [84, 85]. Even though an idea to exploit the Voronoi diagram in electronic structure calculations has been reported [86], no practical implementation for the electronic structure has been accomplished in this direction until now.

We first extend VFD to solve the Schrödinger / Kohn–Sham equation and the Poisson equation for electronic structures of polyatomic molecules with the all-electron realistic Coulomb potential on multicenter molecular grids. There have been many grid-based approaches suggested to attack the multicenter Coulomb singularity with local grid refinement in real-space: for examples, finite element [87, 88, 89], spectral element [90], curvilinear adaptive coordinate [91, 92], multigrid [93, 94, 95], multiresolution analysis with wavelet [96, 97, 98], multicenter B-spline [99], and a hybrid combination of basis set expansion and discrete variable representation [100] (for more examples, see Ref. [61] and references therein). Also, one of the most popular grid-based methods is the high-order finite difference method with the pseudopotential on uniform
Cartesian grids [101, 102]. Notable features of the proposed VFD method over these previous approaches are summarized as follows: (i) High adaptivity: by means of unstructured grids there is no restriction on local grid refinement for polyatomic molecules regardless of molecular symmetry. (ii) Simplicity: VFD provides a simple and explicit matrix form of the discrete Laplacian operator, which realizes a direct solution of the Schrödinger equation and the Kohn–Sham equation on unstructured grids, as well as a simple implementation of the Poisson equation. (iii) No massive integration: the potential matrix is given by a value at each grid and the Hamiltonian matrix is constructed without any integration. (iv) Realistic Coulomb potential: VFD allows us to solve the realistic Coulomb potential in 3D rather than model potentials in order to correctly simulate the short- and long-range features of the Coulomb potential. Furthermore, it can be extended for the time-dependent calculations with capturing accuracy of the bound states and expansibility to the continuum states, because it does not need massive integration for potentials at each time step in time-propagation.

2.2 Voronoi-cell finite difference method

2.2.1 Voronoi discretization

Given an arbitrarily distributed grid-point set \( \{ \mathbf{r}_i \} \) in \( n \)-dimensions, a Voronoi cell surrounding a grid of \( \mathbf{r}_i \) is defined by a set of points that are closer to \( \mathbf{r}_i \) than to any other grids [78],

\[
T_i \equiv \{ \mathbf{r} \in \mathbb{R}^n : d(\mathbf{r}, \mathbf{r}_i) \leq d(\mathbf{r}, \mathbf{r}_j) \text{ for } \forall j \neq i \},
\]  

(2.1)
where \( d(\mathbf{r}_i, \mathbf{r}_j) \) is a distance between two points \( \mathbf{r}_i \) and \( \mathbf{r}_j \). It is well known that the Voronoi diagram is uniquely defined for a given grid-point set [78]. Thus from the Voronoi diagram the whole space is uniquely discretized into Voronoi cells and each grid point is enclosed by cells. Figure 2.1 shows one example of the Voronoi diagram in the 2-dimensional (2D) case and some related symbols that are defined as follows.

The Voronoi cell is denoted as \( T_i \) encapsulating the \( i \)th grid, and its volume is given by \( v_i \). A Voronoi facet \( s_{ij} \) is the surface where two adjacent \( T_i \) and \( T_j \) meet together. Note that the Voronoi facet is a line in 2D (also called the Voronoi edge) as shown in Fig. 2.1 and a polygon plane in 3D. \( h_{ij} \) is a distance between the \( i \)th and \( j \)th grids,

\[
h_{ij} = \|\mathbf{r}_j - \mathbf{r}_i\|. \tag{2.2}
\]

One of the Voronoi properties is that \( s_{ij} \) is the perpendicular bisector of \( h_{ij} \). A natural neighbor [103] is defined by the fact that if two grids share a common
Voronoi facet, they are natural neighbors. For example, in Fig. 2.1 the grids of 1–5 are natural neighbors of the $i$th grid but the grid of 6 is not. A Voronoi vertex is defined as the point where Voronoi facets converge. In other words, the Voronoi facet between two neighboring grids is surrounded by the Voronoi vertices belonging to the two grids. Therefore, an area of $s_{ij}$ in 3D (or a length in 2D) can be computed using the position of the surrounding vertices. In the 3D case, the area of the polygon is computed by

$$s_{ij} = \frac{1}{2} \left| \sum_{k=1}^{M} \text{sign} \left( p_k - q \right) \times \left( p_{k+1} - q \right) \right|, \quad (2.3)$$

where $\times$ is the cross product, $q = (r_i + r_j)/2$, $M$ is the number of surrounding vertices for $s_{ij}$, and $\{p_k\}$ ($k = 1, \cdots, M$ with $p_1 = p_{M+1}$) are position vectors of the vertices. The sign is given by positive when $p_k, p_{k+1}$, and $q$ are oriented counterclockwise and negative when clockwise. The Voronoi cell $T_i$ is further decomposed into polygonal pyramids that have their apex at the $i$th grid and their base as each Voronoi facet, so $v_i$ can be computed by the sum of volumes of these polygonal pyramids,

$$v_i = \frac{1}{6} \sum_{j}^{\text{neighbors}} h_{ij} s_{ij}, \quad (2.4)$$

where $j$ runs over natural neighboring grids of the $i$th grid.

To summarize, for a given set of arbitrarily distributed grids, the Voronoi discretization is uniquely determined and $v_i, s_{ij},$ and $h_{ij}$ are easily calculated by Voronoi vertices and natural neighboring relations within the Voronoi diagram. For numerical determination of the Voronoi diagram, we use the QHULL package [104], and all calculations are performed in 3D.
2.2.2 Discrete Laplacian operator

The Gauss’ theorem \[105\] states that

\[
\int_V \nabla \cdot F \, dV = \int_S F \cdot n \, dS. \tag{2.5}
\]

From this theorem, the Laplacian acts on a function \(\varphi\) is defined by the integral form in the limit that the volume is small,

\[
\nabla^2 \varphi = \lim_{\int_V dV \to 0} \frac{\int_S \nabla \varphi \cdot n \, dS}{\int_V dV}, \tag{2.6}
\]

where \(n\) is the normal unit vector of the surface \(S\). To find the discrete Laplacian form at a grid \(i\), imagine the Voronoi cell corresponding to the \(i\)th grid. After the Voronoi discretization, the volume in the vicinity of the \(i\)th grid can be given by the Voronoi cell \(T_i\). Then the volume integral is converted into the Voronoi volume \(v_i\),

\[
\int_{V \subset T_i} dV \to v_i, \tag{2.7}
\]

and the surface integral is decomposed into the areas of the Voronoi facets \(s_{ij}\) over the neighboring grid \(j\)’s,

\[
\int_{S \subset \partial T_i} \nabla \varphi \cdot n \, dS \to \sum_{\text{neighbors}} (\nabla \varphi)_i \cdot n_{ij}s_{ij}, \tag{2.8}
\]

where \(\partial T_i\) indicates the boundary surface of \(T_i\). Here the inner product indicates a directional derivative of \(\varphi\), which is given by the projection of \(\nabla \varphi\) on the normal vector of the Voronoi facet. Because a line between neighboring grids \(i\) and \(j\) is perpendicular to the corresponding Voronoi facet, the directional derivative at the \(i\)th grid in the direction to the neighboring grid \(j\) can be evaluated by the
simple difference scheme,

\[
(\nabla \phi)_i \cdot n_{ij} \approx \frac{\phi_j - \phi_i}{h_{ij}}. \tag{2.9}
\]

Thus the discrete Laplacian at the \(i\)th grid in the VFD scheme can be evaluated by \([82, 83]\)

\[
\left(\nabla^2 \phi\right)_i = \frac{1}{v_i} \sum_{j}^{\text{neighbors}} \frac{\phi_j - \phi_i}{h_{ij}} s_{ij}. \tag{2.10}
\]

Note that this scheme relies on two computational approximations: firstly the volume of the Voronoi cell is small in the limit of Eq. (2.6), and secondly the finite difference scheme is used for the directional derivative in Eq. (2.9). Once \(v_i, s_{ij}, \) and \(h_{ij}\) for given grid points are available, one can simply and explicitly compute the Laplacian in the framework of VFD.

From Eq. (2.10), the matrix form of the Laplacian operator \(L\) in VFD is expressed as

\[
L : L_{ij} = \begin{cases} 
-\frac{1}{v_i} \sum_{k}^{\text{neighbors}} s_{ik} h_{ik} & (i = j), \\
\frac{1}{v_i h_{ij}} s_{ij} & (i, j: \text{neighbors}), \\
0 & (\text{otherwise}),
\end{cases} \tag{2.11}
\]

where \(k\) runs over natural neighbors of the \(i\)th grid. Note that \(L\) is not symmetric \((L_{ij} \neq L_{ji})\) due to \(v_i\).

A remarkable distinction between VFD and ordinary finite difference (FD) method with regular uniform grids is that VFD on unstructured grids can accommodate any types of grid distributions. Thus the VFD method is compared with the generalized finite difference (GFD) method \([106, 107]\) that also can accommodate irregular grids. GFD usually employs the Taylor expansion and
solves a linear system of equations to compute the first and second derivative quantities at every grid. Therefore GFD does not provide explicit expressions of the Laplacian matrix elements and in many cases the matrix involved in the linear system of equations becomes ill-conditioned, whereas VFD offers the explicit forms of the Laplacian matrix elements that unconditionally exist.

Also the VFD scheme resembles the finite volume method (FVM) [108, 109, 110] because both are based on the Gauss’ theorem and utilize cell volumes to derive basic formula. However, VFD substitutes the volume integral with the Voronoi volume and the surface integral with the simple finite difference form of the directional derivatives, while FVM generally evaluates those integrals using interpolation and quadrature. As a result, VFD provides the simple and explicit expressions at each grid without additional background grids.

2.2.3 Symmetrization of the Hamiltonian matrix

In this section, we discuss how to solve the time-independent Schrödinger equation with the symmetrized VFD Hamiltonian matrix [51]. One can directly use the discrete Laplacian operator in VFD to solve the Schrödinger equation for one electron,

\[
\left[ -\frac{1}{2} \nabla^2 + u(r) \right] \psi(r) = \varepsilon \psi(r),
\]

where \( u(r) \) is a potential function, \( \psi(r) \) is an eigenfunction, and \( \varepsilon \) is an eigenvalue. Note that the atomic units are used throughout the dissertation, unless otherwise indicated. The reduced mass of the electron is set to the unity in the atomic units. In the matrix representation, the Hamiltonian matrix is given by

\[
H = -\frac{1}{2}L + U,
\]
where \( U \) is a potential matrix and given by diagonal elements evaluated at each grid,

\[
U : U_{ij} = \delta_{ij} u(r_i). \tag{2.14}
\]

Then, the eigenvalue problem to be solved is

\[
HC = CE, \tag{2.15}
\]

where \( C \) is the eigenvector matrix and \( E \) is the diagonal matrix of eigenvalues. Since \( L \) is non-symmetric, it is advantageous to transform \( H \) into a symmetric form to facilitate the eigenvalue solution.

Here we introduce a transformation of \( \tilde{C} = V^{\frac{1}{2}} C \) where \( V \) is given by diagonal elements of Voronoi volumes,

\[
V : V_{ij} = \delta_{ij} v_i, \tag{2.16}
\]

and then \( V^{\frac{1}{2}} \) is given by diagonal elements of \( \sqrt{v_i} \) and \( V^{-\frac{1}{2}} \) by \( 1/\sqrt{v_i} \). When \( C = V^{-\frac{1}{2}} \tilde{C} \) is substituted into Eq. (2.15), one obtains

\[
\left( -\frac{1}{2} L + U \right) V^{-\frac{1}{2}} \tilde{C} = V^{-\frac{1}{2}} \tilde{C} E, \tag{2.17a}
\]

\[
V^{\frac{1}{2}} \left( -\frac{1}{2} L + U \right) V^{-\frac{1}{2}} \tilde{C} = V^{-\frac{1}{2}} \tilde{C} E, \tag{2.17b}
\]

\[
\left( -\frac{1}{2} V^{\frac{1}{2}} L V^{-\frac{1}{2}} + U \right) \tilde{C} = V^{-\frac{1}{2}} \tilde{C} E, \tag{2.17c}
\]

where \( V^{\frac{1}{2}} U V^{-\frac{1}{2}} = U \) is used because both \( U \) and \( V \) are diagonal matrices. Using a similarity transformation of \( L \),

\[
\tilde{L} = V^{\frac{1}{2}} L V^{-\frac{1}{2}}, \tag{2.18}
\]
one obtains a symmetric matrix $\tilde{L}$. The explicit expressions for $\tilde{L}$ elements are

$$
\tilde{L}_{ij} = \begin{cases} 
-1 \frac{\text{neighbors}}{v_i} \sum_k s_{ik} h_{ik} & (i = j), \\
1 \frac{s_{ij}}{\sqrt{v_i v_j} h_{ij}} & (i, j: \text{neighbors}), \\
0 & (\text{otherwise}).
\end{cases}
$$

(2.19)

Note that VFD provides a very sparse matrix because it consists of diagonal elements and nonzero elements only at natural neighboring indexes.

Now one can solve the symmetric eigenvalue problem with $\tilde{\mathbf{H}} = -\frac{1}{2} \tilde{L} + \mathbf{U}$ instead of Eq. (2.15),

$$
\tilde{\mathbf{H}} \tilde{\mathbf{C}} = \tilde{\mathbf{C}} \mathbf{E}.
$$

(2.20)

After solving $\tilde{\mathbf{H}}$, the eigenvectors are recovered by $\mathbf{C} = V^{-\frac{1}{2}} \tilde{\mathbf{C}}$,

$$
c_i^{(k)} = \frac{\tilde{c}_i^{(k)}}{\sqrt{v_i}},
$$

(2.21)

where $c_i^{(k)}$ and $\tilde{c}_i^{(k)}$ are values at the $i$th grid of the $k$th eigenvector of $\mathbf{H}$ and $\tilde{\mathbf{H}}$, respectively. Note that for electronic structure calculations of polyatomic molecules $c_i^{(k)}$ has cusps in the vicinity of nuclear positions due to the Coulomb singularity. If the grid distribution is designed to let $v_i$ be small enough around nuclear positions, the solution of $\tilde{c}_i^{(k)}$ can be smoothed out near cusps of $c_i^{(k)}$ because of Eq. (2.21). A multicenter molecular grid distribution is introduced in Section 2.2.5 for this purpose. The eigenvalues of this real symmetric sparse matrix are numerically determined by the implicitly restarted Lanczos method of ARPACK [111] and the large sparse matrix solver of PARDISO [112].
When a numerical integral is required, for examples, computations of the energy functionals in Section 2.3 or the ionization probability in Section 3.3, a set of Voronoi volumes \( \{v_i\} \) works as weights in the nodal quadrature method \([113]\) without additional background cells or grids. The integral in the VFD scheme is simply evaluated by the summation over all grids,

\[
\int_V f(\mathbf{r})dV \approx \sum_i \frac{f(\mathbf{r}_i)v_i}{\text{all}}. 
\] (2.22)

### 2.2.4 Discrete gradient operator

In this section, we derive a discrete gradient operator in the VFD scheme as the same manner as the Laplacian operator in Section 2.2.2. One can recall an alternative form of the Gauss’ theorem \([105]\),

\[
\int_V \nabla \varphi \, dV = \int_S \varphi \mathbf{n} \, dS. 
\] (2.23)

The gradient is defined in the integral form,

\[
\nabla \varphi = \lim_{\int_V dV \to 0} \frac{\int_S \varphi \mathbf{n} \, dS}{\int_V dV}. 
\] (2.24)

The gradient at the \( i \)th grid is given by the summation over Voronoi facet areas divided by the Voronoi volume after the Voronoi discretization. To evaluate the surface integral over \( S \), \( \varphi \) on \( S \) is approximated to \((\varphi_i + \varphi_j)/2\) on \( s_{ij} \) because \( s_{ij} \) is the perpendicular bisector of \( h_{ij} \). Utilizing \( \sum_j n_{ij} s_{ij} = 0 \) and the normal vector on \( s_{ij} \) by \( n_{ij} = (\mathbf{r}_j - \mathbf{r}_i)/h_{ij} \), one obtain the discrete gradient at the \( i \)th grid in the
VFD scheme as
\[
(\nabla \varphi)_i = \frac{1}{v_i} \sum_j^{\text{neighbors}} \frac{\varphi_j + \varphi_i}{2} n_{ij} s_{ij} = \frac{1}{2v_i} \sum_j^{\text{neighbors}} \frac{\varphi_j s_{ij}(r_j - r_i)}{h_{ij}}.
\]

Note that this expression using the middle point of \( \varphi_i \) and \( \varphi_j \) is different from the gradient operator using the center of mass of the Voronoi facet [114]. The matrix form of the \( x \)-component of the gradient operator \( G^{(x)} \) is expressed as
\[
G^{(x)} : C^{(x)}_{ij} = \begin{cases} 
0 & (i = j), \\
\frac{1}{2v_i h_{ij}} s_{ij}(r_j - r_i) \cdot \hat{e}_x & (i, j: \text{neighbors}), \\
0 & \text{(otherwise)},
\end{cases}
\]

where \( \hat{e}_x \) is the unit vector of the \( x \)-axis. Also \( G^{(y)} \) and \( G^{(z)} \) are defined likewise.

Note that the gradient operator is intrinsically non-symmetric.

### 2.2.5 Multicenter molecular grids

In the real-space grid method, local refinement around nuclear positions is requisite to capture the multicenter Coulomb singularity. The VFD method realizes highly adaptive local refinement with unstructured grids. In the grid generation [68], unstructured refers to the grid system that there is no fixed number for connectivity among grids, while structured means that there is a fixed number for connectivity among grids. Since the unstructured scheme grants us the freedom to choose any arbitrary grid distributions, it may be possible to optimize molecular grids in a highly structured manner, which means that we can design highly adaptive nonuniform molecular grids according to molecu-
lar structures. Even though an optimal molecular grid system may be reflected by the molecular structure, there is no limitation on the coordinate system and the molecular symmetry because the design of molecular grids is based on unstructured grids.

For polyatomic molecular calculations, it is natural and intuitive to consider spherical atomic grids located at nuclear positions and combine them together to locate more grids near each nucleus. Figure 2.2 shows 2D sketches of three different types of multicenter molecular grids in this manner of composite grids. Note that all calculations are done in 3D molecular grid systems.

(a) Non-overlapping composite grids: the atomic grids are combined and the grids in the overlapping region are removed except ones closer to the atom that each grid belongs to. As a result, the sphere of the atomic grids is cut out when it overlaps with others. (b) Overlapping composite grids: all overlapping grids are kept except two grid positions exactly coincide. (c) Squeezed composite grids: to avoid the overlap, the maximum radius of the atomic grids is varied when it meets with others. As a result, the sphere of the atomic grids is squeezed. Among these three types, the non-overlap one has the smallest
number of grids because some grids in the overlap are cut out. The numerical results for three different types will be compared in Section 2.4.

Note that the grid distribution of the overlapping composite grids in this manner is exactly matched to the one used in Becke’s basis-set-free DFT calculation [69, 70]. Differences from Becke’s scheme are that in VFD there is no single-center decomposition and the Schrödinger equation is directly solvable on this grid distribution, which remarkably simplifies the numerical algorithm and implementation.

To achieve more local refinement in the vicinity of nuclei, the radial part of the spherical atomic grids is generated by an algebraic mapping function [115] in two different ways. First, the mapping function is given by

$$r(x) = \frac{L}{1 - x} \frac{1 + x}{1 - x} \quad (-1 < x < 1),$$  \hspace{1cm} (2.26)

where $L$ is a mapping parameter and $x$ is defined as uniform grid points in 1D,

$$x_i = \frac{2i}{N_r + 1} - 1 \quad (i = 1, \ldots, N_r),$$  \hspace{1cm} (2.27)

where $N_r$ is the number of radial grids. Thus, the grid location in the radius ranges from $L/(2N_r + 1)$ to $LN_r$, realizing dense grid points near the nuclear position. Second, the mapping function with a finite maximum radius $r_{\text{max}}$ is given by

$$r(x) = \frac{L}{1 - x + \frac{2i}{r_{\text{max}}}} \quad (-1 < x \leq 1),$$  \hspace{1cm} (2.28)

and $x$ is defined as uniform grid points in 1D,

$$x_i = \frac{2i}{N_r} - 1 \quad (i = 1, \ldots, N_r).$$  \hspace{1cm} (2.29)
In this way, the grid location ranges from \( L/\{(1 + L/r_{\text{max}})N_r - 1\} \) to \( r_{\text{max}} \) and still realizes dense grids near the nucleus.

For the angular part of the spherical atomic grids, we adopt angular grid distributions from the Lebedev quadrature \([116, 117, 118]\) and the Womersley quadrature \([119, 120]\). The former has been widely used in multicenter numerical integration \([71, 72]\). Figures 2.3 compares the Lebedev and Womersley grid distributions for \( l_{\text{max}}=32 \) that is the order of angular grids and also indicates the maximum angular momentum. The Lebedev grids retain the octahedral symmetry, so their distribution is to some extent biased around \( x, y, \) and \( z \)-axes. For a given \( l_{\text{max}} \), the number of angular grids is estimated by \( N_{\text{ang}} \approx 4(l_{\text{max}} + 1)^2/3 \). On the other hand, the Womersley grids are designed to be fairly uniform over the sphere, and the number of angular grids is exactly given by \( N_{\text{ang}} = (l_{\text{max}} + 1)^2 \). Since numerical results of eigenvalues for both grid types show a very small difference (\( \ll 5 \times 10^{-5} \) a.u. for \( l_{\text{max}}=10 \)), we will use either the Lebedev scheme or the Womersley scheme case by case. The rule
of thumb is that the Womersley scheme is more efficient because it offers the smaller $N_r$ for a given $l_{\text{max}}$, but the Lebedev scheme is more useful for better accuracy, especially for accurate dipole moments in HHG calculations in Section 3.8, because it preserves the symmetry.

There are only four parameters to build up spherical atomic grids: $N_r$, $L$, and $r_{\text{max}}$ for the radial part, and $l_{\text{max}}$ for the angular part. Also, it is possible to have only three parameters if $r_{\text{max}}$ is not specified. For further calculations, we will use Eqs. (2.26) and (2.27) when $N_r$, $L$, and $l_{\text{max}}$ are specified, and will use Eqs. (2.28) and (2.29) when all four parameters, $N_r$, $L$, $r_{\text{max}}$, and $l_{\text{max}}$ are specified.

Using the non-overlap scheme, we can construct molecular grids from the spherical atomic grids for the VFD calculations. Figure 2.4 shows 2D sketches of four examples of molecular grids: diatomic nitrogen $\text{N}_2$, linear triatomic carbon dioxide $\text{CO}_2$, bent triatomic water $\text{H}_2\text{O}$, and benzene $\text{C}_6\text{H}_6$. One can observe that molecular grids are highly adaptive satisfying more grid points around nuclei.

### 2.3 Application to density-functional theory

Now we apply the VFD method developed in the previous section to accurately compute the electronic structure of many-electron polyatomic molecules using the density-functional theory (DFT) [121]. The DFT states the total energy can be obtained by energy functional [122],

$$E_{\text{total}} = E[\rho] = T_s[\rho] + J[\rho] + E_{\text{ne}}[\rho] + E_{\text{xc}}[\rho^\uparrow, \rho^\downarrow],$$  \hspace{1cm} (2.30)
Figure 2.4: Examples of multicenter molecular grids (2D sketches) used in the Voronoi-cell finite difference method
where \( \rho \) is the total density, and \( \uparrow \) and \( \downarrow \) indicate spin-up and spin-down, respectively. \( T_s[\rho] \) is the noninteracting kinetic energy functional, \( J[\rho] \) is the classical electron–electron repulsion energy functional,

\[
J[\rho] = \frac{1}{2} \int \int \frac{\rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r} d\mathbf{r}',
\]

and \( E_{\text{ne}}[\rho] \) is the nucleus–electron Coulomb interaction energy functional,

\[
E_{\text{ne}}[\rho] = \int \sum_A \frac{Z_A \rho(\mathbf{r})}{|\mathbf{r} - \mathbf{R}_A|} d\mathbf{r},
\]

where \( \mathbf{R}_A \) and \( Z_A \) are the nuclear position and charge of the \( A \)th nucleus, respectively. \( E_{\text{xc}}[\rho_{\uparrow},\rho_{\downarrow}] \) is the exchange–correlation energy functional whose exact form is unknown and it needs to be approximated.

In the Kohn–Sham DFT formulation \([123]\), one solves the Schrödinger-like equation for \( N \)-electron systems,

\[
\left[ -\frac{1}{2} \nabla^2 + u_{\text{eff}, \sigma}(\mathbf{r}) \right] \psi_{i\sigma}(\mathbf{r}) = \epsilon_{i\sigma} \psi_{i\sigma}(\mathbf{r}), \quad (i = 1, 2, \ldots, N_{\sigma})
\]

where \( i \) and \( \sigma \) are the orbital and spin indexes, respectively. \( N_{\sigma} \) is the number of \( \sigma \)-spin electrons and \( N = N_\uparrow + N_\downarrow \). The spin density is given by

\[
\rho_{\sigma}(\mathbf{r}) = \sum_{i=1}^{N_{\sigma}} |\psi_{i\sigma}(\mathbf{r})|^2,
\]

and the total density is given by

\[
\rho(\mathbf{r}) = \sum_{\sigma} \rho_{\sigma}(\mathbf{r}) = \rho_{\uparrow}(\mathbf{r}) + \rho_{\downarrow}(\mathbf{r}).
\]
The effective potential $u_{\text{eff},\sigma}(\mathbf{r})$ consists of three terms,

$$u_{\text{eff},\sigma}(\mathbf{r}) = u_{\text{ne}}(\mathbf{r}) + u_{\text{h}}(\mathbf{r}) + u_{\text{xc},\sigma}(\mathbf{r}).$$  \hfill (2.36)

In the framework of VFD, detailed expressions for each term are as follows.

(i) Nucleus–electron potential: The Coulomb interaction between the electron and nuclei is given by

$$u_{\text{ne}}(\mathbf{r}) = \sum_A \frac{Z_A}{|\mathbf{r} - \mathbf{R}_A|}.$$  \hfill (2.37)

Its matrix form in VFD is simply given by diagonal elements evaluated at each grid.

(ii) Hartree potential: The Hartree potential is given by the classical electron–electron repulsion,

$$u_{\text{h}}(\mathbf{r}) = \int \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}'.$$  \hfill (2.38)

Alternatively, it is computable by solving the Poisson equation,

$$\nabla^2 u_{\text{h}}(\mathbf{r}) = -4\pi \rho(\mathbf{r}).$$  \hfill (2.39)

Its discrete form $u_{\text{h}}$ is simply solvable by a linear system solution of the Laplacian matrix in VFD,

$$\mathbf{L} \mathbf{u}_{\text{h}} = -4\pi \rho,$$  \hfill (2.40)
where \( u_h \) and \( \rho \) are column vector forms of the Hartree potential and the total density represented in every grid.

\[
\begin{align*}
u_h &= (\cdots w_i \cdots)^T, \quad w_i = u_h(r_i), \\
\rho &= (\cdots \rho_i \cdots)^T, \quad \rho_i = \rho(r_i).
\end{align*}
\] (2.41) (2.42)

Here \( L \) is the VFD Laplacian matrix in Eq. (2.11). After substituting the similarity transformation of Eq. (2.18) into Eq. (2.40), one obtains the symmetric form,

\[
\tilde{L}\tilde{u}_h = -\frac{4\pi}{\mathcal{L}}\tilde{\rho},
\] (2.43)

where \( \tilde{u}_h = \mathcal{V}_h^{1/2}u_h \) and \( \tilde{\rho} = \mathcal{V}_h^{1/2}\rho \). The boundary conditions for the Hartree potential (=\(Q/r\) where \(Q\) is the total charge of electrons) are easily incorporated within \( \tilde{L} \). Note that the Poisson equation is solved with the same local grid refinement as the Schrödinger equation or the Kohn–Sham equation. Although multicenter molecular grids are introduced to capture the nucleus–electron Coulomb singularity, one can expect that they also take care of the electron–electron Coulomb singularity because the total electronic density is localized near the nuclear positions.

(iii) Exchange–correlation potential: The simplest form of the exchange–correlation potential is local spin-density approximation (LSDA) \[121\], which consists of the Slater exchange part \[124\],

\[
u_{x,\sigma}^{\text{LSDA}}(r) = -\left[\frac{6}{\pi}\rho_{\sigma}(r)\right]^{1/3},
\] (2.44)

and the Vosko–Wilk–Nusair (VWN) correlation part \[125\] whose practical implementation is found in Ref. \[126\]. Thus, LSDA is also known as SVWN in
many quantum chemistry program packages [126]. However, the conventional exchange–correlation functionals, such as LSDA or generalized gradient approximation (GGA), contain spurious self-interaction energy [121] and they do not possess the correct long-range Coulombic \((-1/r)\) behavior. To take into account the proper long-range potential and remove the self-interaction energy, we adopt the improved Leeuwen–Baerends (LBα) potential [127, 128],

\[
u_{xc,\sigma}^{\text{LB}\alpha}(\mathbf{r}) = \alpha u_{xc,\sigma}^{\text{LSDA}}(\mathbf{r}) + u_{c,\sigma}^{\text{LSDA}}(\mathbf{r}) - \frac{\beta x_\sigma^2(\mathbf{r}) \rho_\sigma^{1/3}(\mathbf{r})}{1 + 3\beta x_\sigma(\mathbf{r}) \log \left(x_\sigma(\mathbf{r}) + \sqrt{x_\sigma^2(\mathbf{r}) + 1}\right)}, \tag{2.45}
\]

where \(x_\sigma(\mathbf{r}) = |\nabla \rho_\sigma(\mathbf{r})|/\rho_\sigma^{4/3}(\mathbf{r})\). Note that \(\alpha\) and \(\beta\) are two adjustable parameters in the LBα potential. \(u_{xc,\sigma}^{\text{LSDA}}\) and \(u_{c,\sigma}^{\text{LSDA}}\) indicate the exchange and correlation potentials of LSDA, respectively, and in this case we use the Perdew–Wang representation for the correlation functional [129]. To assure the asymptotic Coulombic tail of \(-1/r\), the Fermi–Amaldi term is smoothly attached for the long-range distance [130]. By means of the VFD gradient operator in Eq. (2.25), \(x_\sigma(\mathbf{r})\) at the \(i\)th grid is computed by

\[
x_\sigma(\mathbf{r}_i) = \sqrt{\left(g_i^{(x)}\right)^2 + \left(g_i^{(y)}\right)^2 + \left(g_i^{(z)}\right)^2} / \rho_\sigma^{4/3}(\mathbf{r}_i), \tag{2.46}
\]

where \(g_i^{(x)} = [\nabla \rho_\sigma(\mathbf{r}) \cdot \hat{\mathbf{e}}_x]_i = \sum_j G_{ij}^{(x)} \rho_\sigma(\mathbf{r}_j)\) and likewise for \(g_i^{(y)}\) and \(g_i^{(z)}\).
2.4 Accuracy assessment for one-electron systems

First, three different types of molecular grids proposed in Section 2.2.5 are tested. Figure 2.5 compares numerical accuracy for choosing three different types as a function of \( N_r \). The \( y \)-axis represents absolute errors \(|\delta|\) on the ground-state energy of \( \text{H}_2^+ \), defined by differences between computed values with VFD and an exact value \([131]\). \( N_r \) is varied, and \( L=1 \) and \( l_{\text{max}}=20 \) with Lebedev grids are used. As \( N_r \) increases, the ground energies are converged to the exact value. Unresolved errors at large \( N_r \) are due to small \( l_{\text{max}} \), which can be reduced as \( l_{\text{max}} \) increases. The squeezed type always shows better convergence and the overlap type does worse than others, while the non-overlap type becomes close to the squeezed type when \( N_r \) increases. Because the non-overlap type has the smallest total number of grids at given \( N_r \) and \( l_{\text{max}} \), we will use the non-overlap type for further calculations.

![Figure 2.5](image)

Figure 2.5: Comparison of numerical accuracy for different types of molecular grids.
For the simplest one-electron diatomic system, \( \text{H}_2^+ \), we perform accuracy tests with respect to \( N_r \) and \( l_{\text{max}} \). Figures 2.6(a) and (b) plot absolute errors \( |\delta| \) of the ground-state energies of \( \text{H}_2^+ \) as a function of \( N_r \) and \( l_{\text{max}} \), respectively. The internuclear distance is fixed at \( R=2.0 \) a.u. and the Lebedev grids are used for the angular part. Errors are getting smaller as \( N_r \) and \( l_{\text{max}} \) increase, confirming that accuracy of the VFD method is systematically improved by increasing the number of grids to compute electronic structures with the realistic Coulomb potential. Note that low-lying excited states also show similar trends of convergence as the ground state. Figure 2.6 indicates that the ground-state energies are converged up to the fourth decimal place, i.e., \((|\delta| < 5 \times 10^{-4} \text{ a.u.})\) with \( N_r \geq 150 \) and \( l_{\text{max}} \geq 29 \).

Table 2.1 lists electronic energies of low-lying bound states of \( \text{H}_2^+ \) up to first 16 states. All computed energies are lower by less than \( 2.57 \times 10^{-4} \) a.u. from the exact values [131] and all error percentages are less than 0.12%. \( N_r=400 \), \( L=1 \) and \( l_{\text{max}}=47 \) are used with the Lebedev scheme, the non-overlap type of molecular grids, and the mapping function of Eqs. (2.26) and (2.27). The matrix dimension with these parameters is approximately 2 millions \( (N_{\text{total}}=2,086,662) \) but it becomes very sparse because VFD considers only closest natural neighbors of each grid. With ARPACK [111] and PARDISO [112], the computation time to solve selected eigenvalues of the \( 2,086,662 \times 2,086,662 \) matrix takes about 1.2 hours on the lab workstation equipped with two Intel Xeon X5355 (quad core, 2.66GHz) CPUs. For comparison, Table 2.1 includes results from LCAO performed by GAMESS [132] with a huge basis set of aug-cc-pV6Z [133] that converges systematically to the complete basis set limit. All basis sets used in LCAO calculations through the dissertation are retrieved from BASIS SET EXCHANGE [134]. For the ground and first excited states, the LCAO results agree
Figure 2.6: Accuracy on the ground-state energies of $\text{H}_2^+$ computed by VFD.
Table 2.1: Electronic energies (in a.u.) and numerical errors $\delta$ of the ground and excited states of $H_2^+$ at $R=2.0$ a.u. The number in parentheses in orbital symmetry indicates degeneracy.

| Orbital   | Exact [131] | LCAO $\delta$ (a.u.) | $|\delta|$ (%) | VFD $\delta$ (a.u.) | $|\delta|$ (%) |

| $3\sigma_u$ | $-0.137\ 313$ | $6.44 \times 10^{-3}$ | $4.69$ | $-8.55 \times 10^{-5}$ | $0.06$ |
| $5\sigma_g$ | $-0.130\ 792$ | $3.77 \times 10^{-2}$ | $28.82$ | $-1.05 \times 10^{-4}$ | $0.08$ |

well with exact values but there are remarkable discrepancies in higher excited states. This is not surprising because atomic-centered basis functions in LCAO are optimized for the ground-state calculation. On the other hand, VFD results show fair agreements for all ground and excited states.

Next, we compute the simplest one-electron triatomic molecule, $H_3^{++}$, that has the equilateral triangular shape. It has been known that triangular $H_3^{++}$ does not exist [135] but there have been a few results for the ground state with a fixed internuclear distance computed by LCAO and FE [87] as the accuracy assessment beyond atoms and diatomic molecules. We note that there have been recent discussions on existence of triangular $H_3^{++}$ in strong magnetic fields [135]. Table 2.2 lists the ground- and excited-state electronic energies of
Table 2.2: Electronic energies (in a.u.) of the ground and excited states of equilateral triangular H$_3^{++}$ at R=1.68 a.u. $\Delta=E_{\text{VFD}} - E_{\text{LCAO}}$.

H$_3^{++}$ from VFD. For comparison, it includes the results from FE [87] and from LCAO with the aug-cc-pV6Z basis set. The distance between nuclei is fixed at R=1.68 a.u. corresponding to one side of the equilateral triangular shape. For grid parameters, $N_r=400$, $L=1$, and $l_{\text{max}}=41$ with the Lebedev grids are used. Note that all VFD results in Table 2.2 are converged up to the third decimal place with respect to the number of grid points. Differences between VFD and LCAO ($\Delta=E_{\text{VFD}} - E_{\text{LCAO}}$) get increased for higher excited states.

### 2.5 Tests of nodal integration

Since energy functionals for DFT calculations in Eq. (2.30) involve integrals over the whole space, accuracy of VFD nodal quadrature integration of Eq. (2.22) needs to be preliminarily assessed for DFT energy calculations. Table 2.3 shows VFD integrals computed by Eq. (2.22) using converged density from LCAO cal-
Calculations and corresponding exact values of integrals. Error percentages $\delta$ (%) of VFD integrals from exact values are also included. Molecular systems are He, H$_2$, and H$_2$O representing one-, two-, and three-center problems, respectively. For mapping parameters, $L=1$ is used for He and H$_2$, and $L=0.5$ for all nuclei of H$_2$O to refine more grids around a heavy atom which has steeper Coulomb potential. The computed integrals include normalization $n[\bar{\rho}]$, nucleus–electron interaction functional $E_{\text{ne}}[\bar{\rho}]$, and exchange-only local density approximation (XLDA) functional $E_x[\bar{\rho}]$, 

\begin{align*}
n[\bar{\rho}] &= \frac{1}{N_{\text{elec}}} \int \bar{\rho}(\mathbf{r}) d\mathbf{r}, \quad (2.47) \\
E_{\text{ne}}[\bar{\rho}] &= \int \sum_A \frac{Z_A \bar{\rho}(\mathbf{r})}{|\mathbf{r} - \mathbf{R}_A|} d\mathbf{r}, \quad (2.48) \\
E_x[\bar{\rho}] &= -\frac{3}{4} \left( \frac{3}{\pi} \right)^{1/3} \int \bar{\rho}(\mathbf{r})^{4/3} d\mathbf{r}, \quad (2.49)
\end{align*}

where $N_{\text{elec}}$ is the number of electrons. Here, $\bar{\rho}$ is converged Gaussian-type orbital (GTO)-based density which consists of linear combination of GTOs obtained from LCAO calculations with a large basis set of aug-cc-pVQZ [136] that nearly converges to the complete basis set limit [133]. Note that exact values of $n[\bar{\rho}]$ and $E_{\text{ne}}[\bar{\rho}]$ are computed by the analytical integration, while an exact value of $E_x[\bar{\rho}]$ is computed by the multicenter numerical integration [71, 72] and fully converged with large quadrature points ($N_r=288/N_\theta=36/N_\phi=72$). In Table 2.3, the error percentages $\delta$ on normalization of density are less than 0.68% and decrease as the number of grids increases. Also the error percentages on other energy functionals are almost the same as ones on the normalization for the same number of grids. Note that these integration errors do not contaminate
solutions of the eigenvalue problem because the Hamiltonian matrix in VFD is constructed without any integration.

Because eigenvectors in VFD computed by Eqs. (2.20) and (2.21) are always normalized to the unity by means of the VFD integration in Eq. (2.22),

$$\int |\psi^{(k)}(\mathbf{r})|^2 d\mathbf{r} = \sum_i |c_i^{(k)}|^2 v_i = \sum_i |\tilde{c}_i^{(k)}|^2 = 1,$$  \hspace{1cm} (2.50)

the density computed by VFD becomes smaller than the true density by the amount of the normalization factor $n[\bar{\rho}]$. Even though this factor surely diminishes when the number of grids becomes larger, it affects the exchange–correlation and Hartree potentials computed by the density and successively quality of DFT calculations. From this consideration, the density obtained by VFD can be scaled by the normalization factor computed from the GTO-based density in order to correctly compute the exchange–correlation and Hartree potentials,

$$\rho_{\text{norm}} = \rho \times n[\bar{\rho}].$$  \hspace{1cm} (2.51)

For energy functionals, we also use energy functionals with the normalization factor correction to reduce errors occurring at normalization,

$$E_{\text{norm}}[\rho] = \frac{E[\rho_{\text{norm}}]}{n[\bar{\rho}]}.$$  \hspace{1cm} (2.52)

This artificial normalization factor is introduced to compensate for inaccuracy of the simplest nodal quadrature in Eq. (2.22). It is possible to avoid this factor if the high-order scheme of integration is employed.

To examine how this normalization factor on the density affects the DFT results, we compare XLDA energies of H\(_2\) with and without the normalization factor correction in Table 2.4. The internuclear distance of H\(_2\) is fixed at \(R=1.4\) a.u. The table includes the highest occupied molecular orbital (HOMO) and total energies. Exact XLDA values for this diatomic molecule are obtained by the GPS method that accurately computes \(\epsilon_{\text{HOMO}} = -0.331\,463\) a.u. and \(E_{\text{total}} = -1.043\,685\) a.u. with only 20 and 6 grid points for the \(\zeta\) and \(\eta\) coordinates in the prolate spheroidal coordinates [137]. Note that the HOMO and total energies are getting close to exact values no matter whether the normalization factor correction is included or not. However, the results with the correction show faster convergency than ones without the correction and reach sufficient accuracy with very limited number of grid points.

Table 2.4: XLDA energies (in a.u.) of H\(_2\) at \(R=1.4\) a.u.

2.6 Electronic structure calculations of polyatomic molecules

In the previous sections, we have shown that VFD for one-electron systems provides an accurate and efficient Schrödinger equation solver for polyatomic molecules involving the multicenter Coulomb singularity, and developed VFD implementation for DFT including the normalization factor correction for accurate energy functional calculations. Now we explore the capability of the VFD method to perform DFT calculations of polyatomic molecules, and the importance of the self-interaction-correction DFT for accurate electronic structures.

For molecular geometries, we use experimental equilibrium geometries for the bond length ($R$) and the bond angle ($\angle$):

(i) $\text{N}_2$: $R(\text{N–N})=2.074$ a.u. [138],

(ii) $\text{F}_2$: $R(\text{F–F})=2.668$ a.u. [138],

(iii) $\text{CO}_2$: $R(\text{C–O})=2.196$ a.u. [139] and $\angle(\text{O–C–O})=180^\circ$,

(iv) $\text{H}_2\text{O}$: $R(\text{O–H})=1.810$ a.u. and $\angle(\text{H–O–H})=104.48^\circ$ [140],

(v) $\text{NH}_3$: $R(\text{N–H})=1.913$ a.u. and $\angle(\text{H–N–H})=106.67^\circ$ [139],

(vi) $\text{CH}_4$: $R(\text{C–H})=2.054$ a.u. [141] and $\angle(\text{H–C–H})=109.471^\circ$,

(vii) $\text{C}_6\text{H}_6$: $R(\text{C–C})=2.640$ a.u. and $R(\text{C–H})=2.048$ a.u. [139].

First, we present LSDA results for $\text{N}_2$, $\text{H}_2\text{O}$, and $\text{C}_6\text{H}_6$ molecules to assess numerical accuracy of the VFD method for the DFT calculations. The LSDA potential is chosen for the accuracy test because it is the simplest potential and has been widely implemented in many quantum chemistry programs. Table 2.5
shows LSDA orbital and total energies computed by VFD and other calculations. FD indicates the fourth-order finite difference method on uniform equal-spacing grids performed by OCTOPUS [142] with the realistic Coulomb potentials. The LCAO results is performed by GAMESS [132] with aug-cc-pVQZ [136] for N\textsubscript{2} and H\textsubscript{2}O; and 6-311++G(3df,3pd) [143] for C\textsubscript{6}H\textsubscript{6}. Note that these LCAO results are nearly converged to the complete basis set limit. The GPS results for diatomic N\textsubscript{2} [66] are also included for comparison. To keep consistency, the internuclear distance of N\textsubscript{2} in this table is \( R(\text{N–N}) = 2.072 \) a.u. following Ref. [66], and then the LCAO values for N\textsubscript{2} are almost exactly matched with the GPS results. The computational parameters for VFD are \( N_r = 300, L = 0.5 \), and \( l_{\text{max}} = 32 \) with the Lebedev scheme for all nuclei of N\textsubscript{2} and H\textsubscript{2}O; and \( N_r = 200, L = 0.5 \), and \( l_{\text{max}} = 26 \) with the Lebedev scheme for all nuclei of C\textsubscript{6}H\textsubscript{6}.

In Table 2.5, one can see that the valence-electron orbital energies by VFD are comparable to ones by LCAO within less than 0.003 a.u., while the core-electron orbital energies show discrepancies of 0.005–0.010 a.u. For the total energy, the VFD results successfully reproduce the LCAO results by 0.030–0.039 a.u. (0.01–0.04\%) deviations. On the other hand, the conventional FD on uniform grids is not adequate to handle the Coulomb singularity, so affecting orbital and total energies significantly. For N\textsubscript{2}, the valence-electron orbital energies by FD are deviated from the LCAO values by 0.004–0.049 a.u., the core-electron orbital energies by 0.993 a.u., and the total energy by 5.402 a.u. (5.0\%). The total energy for H\textsubscript{2}O differs from the LCAO value by 1.626 a.u. (2.1\%) and for C\textsubscript{6}H\textsubscript{6} the deviation is 11.521 a.u. (5.0\%). Moreover, FD with equal-spacing grids unavoidably uses a very large number of grid points to resolve the Coulomb singularity. For the N\textsubscript{2} case, the FD grid parameters are \( \Delta x = 0.1 \) a.u. and \( r_{\text{max}} = 10 \) a.u., corresponding to \( N_{\text{total}} = 4,187,857 \). In the mean-

time, the VFD grid parameters used for $N_2$ produce $N_{\text{total}}$=592,532 and the maximum radius becomes 150 a.u. Therefore, VFD utilizes about 7 times less grids covering $15^3$ times larger computational spaces than FD. Note that the proposed VFD method is the first-order scheme in the sense that it considers only nearest natural neighboring grids, while FD used here is the fourth-order scheme. Nonetheless, the numerical accuracy and efficiency of VFD are superior to ones of FD, mainly due to the benefit of the highly adaptive multicenter molecular grids.

Next, we present self-interaction-free DFT results showing considerable improvement on the electronic structure of atoms and molecules. Analogue to Koopmans’ theorem [144] for the Hartree–Fock approximation, orbital energies from the Kohn–Sham equation in Eq. (2.33) are comparable to the experimental vertical ionization potentials when the self-interaction-correction term is taken into account [145, 146]. We present orbital binding energies ($-\epsilon$) of a couple of diatomic molecules in Table 2.6, several small polyatomic molecules in Table 2.7, and benzene in Table 2.8, calculated by the VFD method with the LSDA and LBα potentials, in comparison with experiments. In Tables 2.6–2.8, we use the unit of electron volts for better comparison with experiments. The computational parameters in VFD are $N_r$=300, $L=0.5$ a.u., $r_{\text{max}}=20$ a.u., and $l_{\text{max}}=25$ with the Womersley scheme for all molecular cases, except $N_r=200$ for the benzene case. For the LBα parameters, we use $\alpha=1.19$ and $\beta=0.01$ for all cases.

For $N_2$ and $F_2$ in Table 2.6, we compare the VFD values with the GPS results, which provides machine accuracy for atoms and diatomic molecules [67]. The LBα valence orbital energies by VFD are almost exactly matched with the GPS values [147], again ensuring the numerical accuracy of the VFD method.

For all molecular cases in Tables 2.6–2.8, the LBα values are comparable with experimental vertical ionization potentials [148, 149, 150, 151, 152, 153, 154, 155, 156]. LBα valence orbital energies computed by VFD are close to experimental values. For HOMO of N₂, F₂, H₂O, NH₃, and CH₄, the difference of the LBα energy and the experimental value is less than 0.3 eV. For HOMO of CO₂ and C₆H₆, the difference is 0.9 and 1.4 eV, respectively. Note that conventional LSDA functional without the self-interaction correction cannot describe electronic structure and ionization potential correctly. In other words, LSDA valence orbital energies are too weakly bound for all molecules.

2.7 Extension to the high-order scheme

Development of the VFD method in Section 2.2 is regarded as the first-order scheme in the sense that it considers only nearest natural neighboring grids. In the conventional finite difference (FD) method, numerical accuracy can be improved by including next grid points in the FD stencil. Fornberg and Sloan [157] and Fornberg [158] showed that increasing-order FD method in 1D becomes close toward the pseudospectral method when all grids are globally included in the stencil and its grid distribution is matched to the same distribution in the pseudospectral method. Analogue to the conventional FD method, we will show that numerical accuracy of the VFD method can be systematically improved by including further neighboring grids in the numerical scheme, i.e., neighbors of neighbors, neighbors of neighbors of neighbors, and so on. In this section, we analyze the numerical accuracy of VFD by the Taylor expansion,
and develop the high-order VFD scheme of the Laplacian operator by including further neighboring grids.

We start from the Laplacian definition in the integral form in Eq. (2.6),

\[ \nabla^2 \varphi = \lim_{V \to 0} \frac{\int_S \nabla \varphi \cdot n \, dS}{\int_V dV}. \tag{2.53} \]

Let \( v \) be a volume of space computed by the volume integral and \( f(v) \) be the surface integral as a function of \( v \),

\[ \begin{align*}
    v &= \int_V dV \quad \text{and} \quad f(v) = \int_S \nabla \varphi \cdot n \, dS. \\
\end{align*} \tag{2.54} \]

Trivially, \( f(0) = 0 \). Then, the Laplacian is alternatively expressed by the first derivative of \( f(v) \) with respect to \( v \) at \( v = 0 \),

\[ \nabla^2 \varphi = \lim_{v \to 0} \frac{f(v) - f(0)}{v - 0} = f'(0). \tag{2.55} \]

To compute the first derivative \( f'(0) \) with truncation errors, one employs the Taylor expansion near \( v = 0 \),

\[ f(v) = f(0) +vf'(0) + \frac{v^2}{2!}f''(0) + \frac{v^3}{3!}f^{(3)}(0) + \cdots. \tag{2.56} \]

Note that error analysis in the conventional FD usually makes use of a grid spacing, whereas this approach utilizes the Taylor expansion with respect to a grid volume that surely includes information of adjacent neighboring grids. From the Taylor expansion in Eq. (2.56), \( f'(0) \) can be expressed by higher-order
terms with truncation errors,

\[
f'(0) = \frac{1}{v} \left[ f(v) + O(v^2) \right] \tag{2.57a}
\]

\[
= \frac{1}{v} \left[ f(v) - \frac{v^2}{2!} f''(0) + O(v^3) \right] \tag{2.57b}
\]

\[
= \frac{1}{v} \left[ f(v) - \frac{v^2}{2!} f''(0) - \frac{v^3}{3!} f^{(3)}(0) + O(v^4) \right] \tag{2.57c}
\]

\[\vdots\]

\[
= \frac{1}{v} \left[ f(v) - \sum_{k=2}^{n} \frac{v^k}{k!} f^{(k)}(0) + O(v^{n+1}) \right]. \tag{2.57d}
\]

To compute \(f'(0)\) with high-order accuracy, one needs to evaluate the volume \(v\), the surface integral \(f(v)\) and high-order derivatives \(f^{(k)}(0)\).

After Voronoi discretization in Section 2.2.1, one can rewrite discretized quantities of \(v\) and \(f(v)\) as follows. Let \(v_i\) be a discretized version of \(v\), and \(F(v_i)\) be a discretized version of \(f(v)\) at \(v = v_i\). From Eqs. (2.4), (2.8), and (2.9),

\[
v_i = \frac{1}{6} \sum_{j \in n_i} h_{ij} s_{ij}, \tag{2.58}
\]

\[
F(v_i) = \sum_{j \in n_i} \frac{\varphi_j - \varphi_i}{h_{ij}} s_{ij}. \tag{2.59}
\]

where \(n_i\) represents a set of natural neighbors of the \(i\)th grid, and \(j \in n_i\) indicates that \(j\) is one of neighbors of the \(i\)th grid. Note that \(F(v_i)\) requires the summation over nearest neighboring grids only. From the property of the surface integral, \(F\) has additivity property,

\[
F(v_i + v_j) = F(v_i) + F(v_j), \tag{2.60}
\]
where $v_i$ and $v_j$ do not overlap.

For convention, one can define sets of further outer neighbors (high-order neighbors) as

$n_i^{(1)}$: nearest natural neighbors of the $i$th grid ($= n_i$)

$n_i^{(2)}$: outer neighbors of $n_i^{(1)}$; $n_i^{(2)} = \{k : k \in n_j^{(1)} \text{ for } j \in n_i^{(1)}, k \neq i\}$

\[ \vdots \]

$n_i^{(m)}$: outer neighbors of $n_i^{(m-1)}$; $n_i^{(m)} = \{k : k \in n_j^{(1)} \text{ for } j \in n_i^{(m-1)}, k \notin n_i^{(m-2)}\}$.

Here $n_i^{(2)}$ indicates non-duplicated outer neighbors of neighbors of the $i$th grid, and all high-order neighbors can be defined in this recursive way. Figure 2.7 displays these high-order neighbors around the $i$th grid (center). Then, $m$th-
order neighboring volume \( v_i^{(m)} \) can be defined as,

\[
v_i^{(m)} = \sum_{j \in n_i^{(m)}} v_j. \tag{2.62}
\]

Also \( V_i^{(m)} \) is defined as the total volume inside outer neighbors including outer neighbors themselves,

\[
V_i^{(1)} = v_i^{(1)} + v_i
\]
\[
V_i^{(2)} = v_i^{(2)} + V_i^{(1)}
\]
\[
\vdots
\]
\[
V_i^{(m)} = v_i^{(m)} + V_i^{(m-1)}. \tag{2.63}
\]

Now, let us consider \( n \)th-order derivatives, \( F^{(n)}(0) \). We can employ the simple finite difference scheme to compute derivatives and further neighbors to achieve the high-order derivatives. In other words, the first derivative is evaluated by the simple finite difference scheme,

\[
F'(0) = \frac{F(v_i) - F(0)}{v_i - 0} = \frac{F(v_i)}{v_i}, \tag{2.64}
\]

and then the second derivative is given by the derivative of the first-order derivative,

\[
F''(0) = \frac{F'(v_i) - F'(0)}{v_i - 0}, \tag{2.65}
\]
where \( F'(0) \) is previously computed and \( F'(v_i) \) will be evaluated with further neighbors using the additivity of \( F \),

\[
F'(v_i) = \frac{F(V_i^{(1)}) - F(v_i)}{V_i^{(1)} - v_i} = \frac{F(v_i^{(1)}) + F(v_i) - F(v_i)}{v_i^{(1)} + v_i - v_i} = \frac{F(v_i^{(1)})}{v_i^{(1)}}. \tag{2.66}
\]

Thus, \( F''(0) \) is finally evaluated by,

\[
F''(0) = \frac{F(v_i^{(1)})}{v_i v_i^{(1)}} - \frac{F(v_i)}{v_i^2}, \tag{2.67}
\]

where \( F(v_i^{(1)}) \) is easily computed by \( F(v_i^{(1)}) = F(\sum_j v_j) = \sum_j F(v_j) \) where \( j \in n_i^{(1)} \) using the additivity of \( F \). In the general cases, these expressions yield a recursive equation with respect to two indexes, \( n \) and \( m \).

\[
F^{(n)}(V_i^{(m)}) = \frac{F^{(n-1)}(V_i^{(m+1)}) - F^{(n-1)}(V_i^{(m)})}{V_i^{(m+1)} - V_i^{(m)}}
= \frac{F^{(n-1)}(V_i^{(m+1)}) - F^{(n-1)}(V_i^{(m)})}{v_i^{(m+1)}} \quad (n \geq 1 \text{ and } m \geq -1). \tag{2.68}
\]

In the special cases, \( V_i^{(0)} = v_i^{(0)} = v_i \) and \( V_i^{(-1)} = 0 \). Evaluation of the \( n \)th derivative at a given volume requires the \((n-1)\)th derivative at both the same volume and further neighboring volume. After simplifying the recursive equation with respect to \( m \),

\[
F^{(n)}(V_i^{(m)}) = (-1)^{n+1} \frac{F(v_i^{(m+1)})}{(v_i^{(m+1)})^n} + \sum_{k=1}^{n-1} (-1)^{n-k+1} \frac{F^{(k)}(V_i^{(m+1)})}{(v_i^{(m+1)})^{n-k}}. \tag{2.69}
\]
Especially, \( F^{(n)}(0) \) is expressed by,

\[
F^{(n)}(0) = \sum_{k=0}^{n-1} (-1)^{n-k+1} \frac{F^{(k)}(v_i)}{(v_i)^{n-k}}.
\]

(2.70)

Using Eq. (2.69) and (2.70), \( F^{(n)}(0) \) can be expressed with \( F(v_i^{(m)}) \) which is easily computable by the additivity of \( F \). The solution has the following form,

\[
F^{(n)}(0) = \sum_{k=0}^{n-1} \left[ (-1)^{n-k+1} \frac{F^{(k)}(v_i)}{\prod_{l=0}^{k} v_i^{(l)}} \left( \alpha_0^{+ \cdots + \alpha_l} \sum_{\alpha_0, \alpha_1, \ldots, \alpha_l} \frac{1}{(v_i^{(0)})^{\alpha_0} (v_i^{(1)})^{\alpha_1} \cdots (v_i^{(l)})^{\alpha_l}} \right) \right],
\]

(2.71)

where \( \alpha_0, \alpha_1, \ldots, \alpha_l \) are all integers \( \geq 0 \). For instance, the 1st- to the 4th-order derivatives are expressed as follows,

\( F'(0) = \frac{F(v_i)}{v_i} \) \hspace{1cm} (2.72a)

\( F''(0) = -\frac{F(v_i)}{v_i^2} + \frac{F(v_i^{(1)})}{v_i v_i^{(1)}} \) \hspace{1cm} (2.72b)

\( F^{(3)}(0) = \frac{F(v_i)}{v_i^3} - \frac{1}{v_i v_i^{(1)}} \left( \frac{1}{v_i} + \frac{1}{(v_i^{(1)})^{2}} \right) F(v_i^{(1)}) + \frac{F(v_i^{(2)})}{v_i v_i^{(1)} v_i^{(2)}} \) \hspace{1cm} (2.72c)

\( F^{(4)}(0) = \frac{F(v_i)}{v_i^4} + \frac{1}{v_i v_i^{(1)}} \left( \frac{1}{v_i^2} + \frac{1}{v_i v_i^{(1)}} + \frac{1}{(v_i^{(1)})^{2}} \right) F(v_i^{(1)}) + \frac{F(v_i^{(2)})}{v_i v_i^{(1)} v_i^{(2)}} + \frac{F(v_i^{(3)})}{v_i v_i^{(1)} v_i^{(2)} v_i^{(3)}}. \) \hspace{1cm} (2.72d)

From the high-order expressions in Eq. (2.57) using discretized evaluations of the high-order derivatives and further natural neighbors in Eq. (2.71), one can compute the Laplacian at the \( i \)th grid with the high-order precision. The first-
order VFD scheme yields

\[
\left( \nabla^2 \varphi \right)_i = \frac{1}{v_i} \sum_{j \in n_i^{(1)}} \frac{\varphi_j - \varphi_i}{h_{ij}} s_{ij},
\]  

(2.73)

which is reduced to Eq. (2.10). The second-order VFD expression is

\[
\left( \nabla^2 \varphi \right)_i = \left[ 1 + \frac{1}{2!} \left( 1 + \frac{1}{v_i} \right) \frac{1}{v_i} \sum_{j \in n_i^{(1)}} \frac{\varphi_j - \varphi_i}{h_{ij}} s_{ij} \right. \\
\left. + \left[ -\frac{1}{2!} + \frac{1}{3!} \left( 1 + \frac{1}{v_i} \right) \right] \frac{1}{v_i} \sum_{j \in n_i^{(1)}} \sum_{k \in n_i^{(1)}} \frac{\varphi_k - \varphi_j}{h_{jk}} s_{jk} \right] \\
- \frac{1}{3!} \frac{v_i}{v_i^{(1)}} \frac{1}{v_i^{(2)}} \sum_{j \in n_i^{(2)}} \sum_{k \in n_i^{(1)}} \frac{\varphi_k - \varphi_j}{h_{jk}} s_{jk}.
\]  

(2.74)

The third-order VFD is

\[
\left( \nabla^2 \varphi \right)_i = \left[ 1 + \frac{1}{2!} - \frac{1}{3!} \right] \frac{1}{v_i} \sum_{j \in n_i^{(1)}} \frac{\varphi_j - \varphi_i}{h_{ij}} s_{ij} \\
+ \left[ -\frac{1}{3!} \left( 1 + \frac{1}{v_i} \right) \left( 1 + \frac{1}{v_i} \right) \frac{1}{v_i} \sum_{j \in n_i^{(1)}} \sum_{k \in n_i^{(1)}} \frac{\varphi_k - \varphi_j}{h_{jk}} s_{jk} \right] \\
- \frac{1}{3!} \frac{v_i}{v_i^{(1)}} \frac{1}{v_i^{(2)}} \sum_{j \in n_i^{(2)}} \sum_{k \in n_i^{(1)}} \frac{\varphi_k - \varphi_j}{h_{jk}} s_{jk}.
\]  

(2.75)

The fourth-order VFD is

\[
\left( \nabla^2 \varphi \right)_i = \left[ 1 + \frac{1}{2!} - \frac{1}{3!} + \frac{1}{4!} \right] \frac{1}{v_i} \sum_{j \in n_i^{(1)}} \frac{\varphi_j - \varphi_i}{h_{ij}} s_{ij} \\
+ \left[ \frac{1}{2!} + \frac{1}{3!} \left( 1 + \frac{1}{v_i} \right) \frac{1}{v_i} \left( 1 + \frac{1}{v_i} \right) \frac{1}{v_i} \sum_{j \in n_i^{(1)}} \sum_{k \in n_i^{(1)}} \frac{\varphi_k - \varphi_i}{h_{jk}} s_{jk} \right] \\
+ \left[ -\frac{1}{3!} \frac{v_i}{v_i^{(1)}} + \frac{1}{4!} \left( \frac{v_i^{(1)}}{v_i} + \frac{v_i^{2}}{v_i^{(1)}} + \frac{v_i^{2}}{v_i^{(1)}} \frac{1}{(v_i^{(1)})^2} \right) \right] \frac{1}{v_i} \sum_{j \in n_i^{(2)}} \sum_{k \in n_i^{(1)}} \frac{\varphi_k - \varphi_i}{h_{jk}} s_{jk} \\
- \frac{1}{4!} \frac{v_i^{2}}{v_i^{(1)}} \frac{1}{v_i^{(3)}} \sum_{j \in n_i^{(3)}} \sum_{k \in n_i^{(1)}} \frac{\varphi_k - \varphi_i}{h_{jk}} s_{jk}.
\]  

(2.76)
The high-order VFD formulation throughout Eqs. (2.73)–(2.76) provides an explicit expression for all grid points. It includes evaluations of the neighboring volumes and the surface integral for nearest neighboring grids as well as finding further high-order neighbors. The high-order neighbors are determined by the recursive manner of finding nearest neighbors. Thus, it is worthwhile to note that the VFD method is systematically improvable by recursive self-enhancement.

We first perform the electronic structure calculations of $H^+_2$ by means of the high-order VFD method on multicenter molecular grids in Section 2.2.5. Figures 2.8(a) and (b) shows errors $\delta$ of the ground-state energies of $H^+_2$ as a function of $N_r$ and $l_{\text{max}}$, respectively. For VFD computational parameters, $l_{\text{max}}=15$ is fixed for Fig. 2.8(a) and $N_r=50$ is fixed for Fig. 2.8(b). The mapping parameter is $L=1$ for both cases and the Lebedev scheme is used for the angular grid distribution. The high-order schemes remarkably improve convergency with respect to both radial grids and angular grids. For instances, the number of grid points to be required for convergence up to the third decimal place, i.e., $|\delta| < 5 \times 10^{-4}$ a.u., is dramatically reduced as the higher-order scheme is used:

(i) 1st-order VFD: $N_r \geq 150$ and $l_{\text{max}} \geq 29 \rightarrow N_{\text{tot}}=293,932$

(ii) 2nd-order VFD: $N_r \geq 60$ and $l_{\text{max}} \geq 15 \rightarrow N_{\text{tot}}=34,146$

(iii) 3rd-order VFD: $N_r \geq 30$ and $l_{\text{max}} \geq 12 \rightarrow N_{\text{tot}}=11,236$

(iv) 4th-order VFD: $N_r \geq 25$ and $l_{\text{max}} \geq 10 \rightarrow N_{\text{tot}}=6,879$

Although the proposed high-order scheme is very promising for solving the Schrödinger equation, there exist several limitations, especially to be extended for DFT and TDDFT calculations. First, error analysis for each high-
Figure 2.8: Accuracy on the ground-state energies of H$_2^+$ computed by high-order VFD.
order derivative needs to be examined. Second, the Laplacian matrix is not symmetric any more. Third, the scheme is not accompanied by high-order accuracy integration. In Section 2.2.3, we have seen that the symmetrization is done with the weight matrix used in integration. In the first-order scheme, it was only the diagonal Voronoi volume matrix. In this manner, we expect there is a close connection between high-order integration and symmetrization. For wide applications of the high-order VFD scheme, these points need to be further investigated.
Chapter 3

Time-dependent Voronoi-cell finite difference method for probing multiphoton electron dynamics of polyatomic molecules

We first develop a new grid-based time-dependent method to investigate strong-field multiphoton processes of polyatomic molecules in intense ultrashort laser fields. The electronic structure of polyatomic molecules is treated by the density-functional theory (DFT) with proper long-range potential and the Kohn–Sham equation is accurately solved by means of the Voronoi-cell finite difference method on nonuniform and highly adaptive multicenter molecular grids. This method is generalized to the time-dependent problems with the split-operator time-propagation technique in the energy representation, allowing accurate and efficient non-perturbative treatment of attosecond electronic dynamics in strong fields. The new procedure is applied to the study of multiphoton ionization (MPI), photoelectron angular distribution (PAD), and high-order harmonic generation (HHG) of several polyatomic molecules in intense linearly-polarized and ultrashort laser fields with arbitrary field–molecule orientation.
Our results demonstrate the importance of the symmetries and dynamics of all contributing molecular orbitals, not only the highest-occupied molecular orbital (HOMO) but also inner valence orbitals. This feature suggests a new way to selectively probe individual orbitals in strong-field electronic dynamics.

3.1 Molecules in strong laser fields: molecular alignment and multielectron effects

The study of molecules in intense laser fields is a subject of much current significance in atomic, molecular, and optical physics [29]. Recent advances of laser technology enable us to align ensembles of molecules periodically by creating a coherent superposition of rotational states [159, 160]. This laser-induced molecular alignment capability has significant impact on strong-field molecular physics, leading to impressive applications such as tomographic imaging of molecular orbitals [25], quantum interference [161] and multiple orbital contribution [162] in high harmonic generation (HHG), and time-resolved photoelectron angular distribution (PAD) [163]. It also has been possible to measure multiphoton ionization (MPI) [164, 165], HHG [166], and PAD [167] as a function of the angle between the polarization of linearly-polarized laser field and the orientation of aligned linear molecules. In particular, the field–molecule orientation dependence of MPI has attracted much attention because not only the ionization mechanism plays a fundamental role in strong-field processes but also the molecular alignment may offer additional degree of freedom to control molecular processes. Also the orientation-resolved HHG of aligned molecules has attracted much current interests related to molecular imaging [26], which
allows for probing the electronic structures and dynamics, for example, the tomographic picture of molecular orbitals [25].

Most of the recent theoretical studies of MPI are based on approximated models such as the molecular Ammosov–Delone–Krainov (ADK) [168] and Keldysh–Faisal–Reiss [169] models, which usually consider only the highest-occupied molecular orbital (HOMO) contribution and neglect the multielectron dynamics from multiple orbitals. However, there have been several recent experimental studies showing significant discrepancies between experimental observations and approximated models, for example, the non-suppression of F₂ MPI [170, 171] and the orientation dependence of CO₂ MPI [164, 165], etc. More recently, the importance of contribution to HHG and MPI from the inner orbital just below HOMO has been experimentally demonstrated in N₂ [162], N₂O₄ [172], and CO₂ [173] which cannot be explained by the approximated models. Thus, it is an important and timely task to develop more comprehensive and accurate theoretical description of strong-field electronic dynamics including electron correlation and multielectron responses. Along this direction, we note that the self-interaction-free time-dependent density-functional theory (TDDFT) has been recently developed and successfully applied to a number of studies of atomic and diatomic molecular processes in intense laser fields [49, 147, 174, 175, 176], with results in good agreement with experiments. Here we present TDDFT studies of polyatomic molecular processes in intense laser fields for the first time by new development of a grid-based time-dependent method.
3.2 Time-dependent Voronoi-cell finite difference method

We develop a time-dependent Voronoi-cell finite difference (TDVFD) method as an extension of VFD to the time domain, incorporating with the second-order split-operator technique in the energy representation [41, 50]. Let us consider the time-dependent Schrödinger equation with a time-dependent potential \( u(r,t) \),

\[
i \frac{\partial}{\partial t} \psi(r,t) = \hat{H}(r,t)\psi(r,t), \tag{3.1}
\]

where \( \hat{H}(r,t) = -\frac{1}{2} \nabla^2 + u(r,t) \). For a numerical time-propagation of Eq. (3.1), \( \hat{H}(r,t) \) can be split into two parts as

\[
\hat{H}(r,t) = \hat{H}_0(r) + \hat{U}(r,t), \tag{3.2}
\]

where

\[
\hat{H}_0(r) = -\frac{1}{2} \nabla^2 + u(r,0), \tag{3.3}
\]

\[
\hat{U}(r,t) = u(r,t) - u(r,0). \tag{3.4}
\]

The unperturbed Hamiltonian \( \hat{H}_0(r) \) is accurately solved by the VFD method and the time-dependent potential \( \hat{U}(r,t) \) is simply given by a diagonal matrix evaluated at each grid in the VFD scheme. Since \( \hat{H}_0(r) \) is already represented in 3D real space in VFD, there is no further sophistication needed regarding the molecular symmetry. Then the second-order split-operator technique for the time-propagation yields

\[
\psi(t + \Delta t) = e^{-i\hat{U}(t)\frac{\Delta t}{2}} e^{-i\hat{H}_0\Delta t} e^{-i\hat{U}(t)\frac{\Delta t}{2}} \psi(t) + O(\Delta t^3), \tag{3.5}
\]
where the coordinate \( r \) is not explicitly expressed for briefness.

In the matrix representation,

\[
f(t + \Delta t) \leftarrow e^{-iU(t)\frac{\Delta t}{2}} e^{-iH_0\Delta t} e^{-iU(t)\frac{\Delta t}{2}} f(t),
\]

(3.6)

where \( f(t) \) is a column vector of the time-dependent wavefunction represented in every grid,

\[
f(t) = (\cdots f_i(t) \cdots)^T; \quad f_i(t) = \psi(r_i, t).
\]

(3.7)

The exponential of the diagonal matrix is trivially obtained by exponentiating every entry on the main diagonal. Since \( U(t) \) is given by a diagonal matrix in VFD, \( \exp[-iU(t)\frac{\Delta t}{2}] \) is simply computable. For \( \exp[-iH_0\Delta t] \), one defines an evolution matrix \( S \) with the spectral decomposition of \( H_0 = \lambda C \lambda^{-1} \) where \( C \) is the eigenvector matrix and \( \lambda \) is the diagonal matrix of eigenvalues in Eq. (2.15),

\[
S = e^{-iH_0\Delta t} = C e^{-i\lambda \Delta t} C^{-1},
\]

(3.8)

where \( \exp[-i\lambda \Delta t] \) is easily computable with the eigenstate energies in the diagonal matrix \( \lambda \).

For the symmetric Hamiltonian \( \tilde{H}_0 \) in Eq. (2.20), the symmetric version is expressed by

\[
\tilde{S} = e^{-i\tilde{H}_0\Delta t} = \tilde{C} e^{-i\tilde{\lambda} \Delta t} \tilde{C}^T,
\]

(3.9)

and then the time-propagation is performed by

\[
\tilde{f}(t + \Delta t) = W(t) \cdot \tilde{S} \cdot W(t) \cdot \tilde{f}(t),
\]

(3.10)
where \( \tilde{f} = \mathbf{V}^{\frac{1}{2}}f \) and \( W(t) = \exp[-i\mathbf{U}(t)\Delta t] \). All operations here are the matrix-vector multiplication and even \( W(t) \) is a diagonal matrix. So, they can be optimized and parallelized with ease on modern computer architectures, for example, through optimized BLAS libraries [177] for a specific processor. The explicit expressions of the \( \tilde{S} \) elements are

\[
\tilde{S} : S_{ij} = \sum_k \tilde{C}_{ik} \tilde{C}_{jk} e^{-i\varepsilon_k \Delta t},
\]

(3.11)

where \( \varepsilon_k \) is the \( k \)th eigenstate energy and \( \tilde{C}_{ik} \) is a value at the \( i \)th grid of the \( k \)th eigenvector of \( \tilde{H} \). We emphasize that this \( \tilde{S} \) is a time-independent complex symmetric matrix and it needs to be constructed only once before the time-propagation, which remarkably reduces the computation time.

This TDVFD scheme in the energy representation is different from the conventional split-operator techniques [178, 179] where \( \hat{H}_0 \) is usually chosen to be the kinetic energy operator solved by the fast Fourier transformation on the uniform grids. The advantages of using our proposed method are (i) highly adaptive molecular grids to solve \( \hat{H}_0 \) as described in Section 2.2.5, and (ii) elimination of the undesirable fast-oscillating high-energy components in the \( \tilde{S} \) matrix [41, 50]. Both features allow us to reduce the number of spatial grids and to speed up the time-propagation considerably. Furthermore, this scheme inherits unconditionally numerical stability and conservation of probability from the original split-operator technique due to the unitary evolution operator [178]. Thus it conserves the norm of the wavefunctions during the time-propagation (for example, errors of the norm are about \( 10^{-10} \) in the field-free case), ensuring the numerical accuracy of ionization probabilities computed from the norm of the wavefunctions in Section 3.3.
3.3 Application to time-dependent density-functional theory

We now consider the solution of a set of time-dependent Kohn–Sham equations for $N$-electron systems in the time-dependent density-functional theory (TDDFT) framework \[180],

$$i \frac{\partial}{\partial t} \psi_{i\sigma}(\mathbf{r}, t) = \left[ -\frac{1}{2} \nabla^2 + u_{\text{eff},\sigma}(\mathbf{r}, t) \right] \psi_{i\sigma}(\mathbf{r}, t), \quad (i = 1, 2, ..., N_\sigma), \quad (3.12)$$

where the time-dependent effective potential is expressed by

$$u_{\text{eff},\sigma}(\mathbf{r}, t) = u_{\text{ne}}(\mathbf{r}) + u_{\text{h}}(\mathbf{r}, t) + u_{\text{xc},\sigma}(\mathbf{r}, t) + F(t) \cdot \mathbf{r}. \quad (3.13)$$

The time-dependent Hartree potential is

$$u_{\text{h}}(\mathbf{r}, t) = \int \frac{\rho(\mathbf{r'}, t)}{|\mathbf{r} - \mathbf{r'}|} d\mathbf{r'}, \quad (3.14)$$

and for the time-dependent exchange–correlation potential we use the adiabatic approximation \[174] with the LB$\alpha$ potential in Eq. \(2.45\),

$$u_{\text{xc},\sigma}(\mathbf{r}, t) = u_{\text{xc},\sigma}^{\text{LB}\alpha}[\rho], \quad (3.15)$$

The correct long-range asymptotic behavior of the LB$\alpha$ potential is crucial for proper DFT treatment of molecular excited and continuum states in strong-field electronic dynamics \[49, 147, 175, 176\]. The last term $F(t) \cdot \mathbf{r}$ is the interaction of an electron with a linearly-polarized external laser field.
To solve Eq. (3.12), we use the TDVFD method described in Section 3.2. In the split-operator technique, \( \hat{H}_0(r) \) and \( \hat{U}(r,t) \) are given by

\[
\hat{H}_0(r) = -\frac{1}{2} \nabla^2 + u_{\text{eff},\sigma}(r,0),
\]

\[
\hat{U}(r,t) = F(t) \cdot r + [u_{\text{xc},\sigma}(r,t) - u_{\text{xc},\sigma}(r,0)] + [u_h(r,t) - u_h(r,0)],
\]

and the time-dependent wavefunction for each spin-orbital is propagated by Eq. (3.5). Through the TDDFT formulation solved by the TDVFD method, we can now explore strong-field electronic dynamics including all molecular spin-orbitals and continuum states.

From the TDDFT solutions, one can compute the time-dependent ionization probability of an individual spin-orbital by

\[
P_{i\sigma}(t) = 1 - n_{i\sigma}(t),
\]

where

\[
n_{i\sigma}(t) = \langle \psi_{i\sigma}(r,t) | \psi_{i\sigma}(r,t) \rangle
\]

is the population or survival probability of the spin-orbital, which is the norm of the time-dependent wavefunction decreasing as a function of \( t \) due to the absorber \([41]\) to prevent spurious reflections at radial boundary and to filter out the ionized wave packet. The time-dependent total survival probability is given by multiplication of all spin-orbital survival probabilities,

\[
n_{\text{total}}(t) = \prod_{i\sigma} n_{i\sigma}(t) = \prod_{i\sigma} [1 - P_{i\sigma}(t)],
\]
and the time-dependent total ionization probability is given by

\[ P(t) = 1 - n_{\text{total}}(t). \]  

(3.21)

Then, the total ionization probability \( P \) after one pulse (at \( t = T \)) can be calculated by

\[ P = 1 - \prod_{i\sigma} [1 - P_{i\sigma}(T)]. \]  

(3.22)

In the limit of small \( P_{i\sigma}(T) \), Eq. (3.22) is reduced to the sum of individual ionization probabilities,

\[ P \approx \sum_{i\sigma} P_{i\sigma}(T). \]  

(3.23)

To calculate HHG spectra, one can compute the time-dependent dipole moment from the TDDFT solutions,

\[ \mathbf{D}(t) = \sum_{i\sigma} \langle \psi_{i\sigma}(\mathbf{r}, t) | \mathbf{r} | \psi_{i\sigma}(\mathbf{r}, t) \rangle, \]  

(3.24)

and then the spectral density \( S(\omega) \) of the radiation energy emitted for all the time for the laser pulses is given by \([67, 181]\)

\[ S(\omega) = \frac{4\omega^4}{6\pi^2c^3} |\tilde{\mathbf{D}}(\omega)|^2, \]  

(3.25)

where \( c \) is the velocity of light and \( \tilde{\mathbf{D}}(\omega) \) is the Fourier transform of the time-dependent dipole moment,

\[ \tilde{\mathbf{D}}(\omega) = \int_{-\infty}^{\infty} \mathbf{D}(t)e^{-i\omega t} dt. \]  

(3.26)

The plot of \( S(\omega) \) as a function of \( \omega \) forms the HHG spectrum.
3.4 Orientation dependence of multiphoton ionization of N$_2$

We perform TDDFT calculations of N$_2$ with arbitrary field–molecule orientation by means of the TDVFD method. The ground-state electronic configuration of N$_2$ is

$$
[\text{core}](2\sigma_g)^2(2\sigma_u)^2(1\pi_u)^4(3\sigma_g)^2,
$$

where [core] is $(1\sigma_g)^2(1\sigma_u)^2$ that corresponds to 1s orbitals of two N’s. All orbitals except the core orbitals participate in the time-propagation.

For time-dependent solutions with the TDVFD method, the most time-consuming part is Eq. (3.10), involving the matrix–vector multiplication. In the VFD and TDVFD schemes, the matrix size is identical to the total number of grid points. Table 3.1 shows LB$_\alpha$ orbital binding energies of N$_2$ with smaller number of grids than one used in Table 2.6: $N_r$=80, $L$=2 a.u., $r_{\text{max}}$=40 a.u., and $l_{\text{max}}$=12 with the Womersley grids, corresponding to the total number of grids $N_{\text{total}}$=21,164. For the LB$_\alpha$ parameters in this case, $\alpha$=1.24 is used to obtain better agreement with experiments. One can see that the LB$_\alpha$ orbital energies with a small number of grids still reproduce the electronic structure of N$_2$ in comparison with experimental vertical ionization potentials [148]. Based on this electronic structure with the matrix size of $N_{\text{total}}$=21,164, we are able to carry out time-dependent calculations within a reasonable computation time.

In order to examine electronic dynamics as a function of the angle between the polarization of the laser field and the orientation of aligned N$_2$, we define the orientation angle as shown in Fig. 3.1(a). Without loss of generality, we assume that the molecular axis coincides with the $z$-axis and the polarization
Table 3.1: Orbital binding energies (in eV) of N\(_2\) computed by VFD with a small number of grids.

Figure 3.1: Molecular geometry and molecular orbital pictures of N\(_2\). The principal axis is the z-axis and the molecular geometry is fixed. Two nitrogen atoms (gray ball) are located in the z-axis. The field polarization axis with respect to the principal axis changes toward the x-axis (\(\Theta\)).
vector of the external field lies in the $xz$-plane, then $\mathbf{F}(t) \cdot \mathbf{r}$ is given by

$$\mathbf{F}(t) \cdot \mathbf{r} = F(t)(x \sin \Theta + z \cos \Theta), \quad (3.27)$$

where $\Theta$ is the orientation angle between the molecular axis and the field polarization axis.

For the sine-squared pulse envelope, we use

$$F(t) = F_0 \sin^2 \left( \frac{\pi t}{T} \right) \sin \omega t, \quad (3.28)$$

where $F_0$ is the peak field amplitude, $\omega$ is the carrier frequency, and $T$ is the pulse duration. During the time-propagation, we use the radial-based absorber function [41] as

$$w(r_c) = \cos \frac{1}{4} \left[ \frac{\pi (r_c - r_0)}{2(r_1 - r_0)} \right] \quad \text{for } r_0 \leq r_c \leq r_1, \quad (3.29)$$

where $r_c$ is a radial distance from the closest nucleus. For laser parameters, we use $\omega=0.0556$ a.u. corresponding to the wavelength 800 nm and $T=20$ optical cycles (o.c.). For computational parameters of time-dependent problems, we use $r_0=15$ a.u., $r_1=25$ a.u., and $\Delta t=0.001$ o.c. corresponding to 2.67 attoseconds. For an one-point calculation of $N_{\text{total}}=21,164$ and $T=20$ o.c. (20,000 time iterations in total), the computation time takes about 10.5 hours on the lab workstation equipped with two Intel Xeon X5355 (quad core, 2.66GHz) CPUs.

Figures 3.1(b)–(e) illustrate individual orbital pictures of $\text{N}_2$ obtained by GAMESS [132] and MACMOLPLT [182]. HOMO ($3\sigma_g$) and HOMO$-2$ ($2\sigma_u$) lie along with the $z$-axis and two degenerate HOMO$-1$ ($1\pi_u, x$ and $1\pi_u, y$) lie in the $xz$- and $yz$-planes. Energetically, the orbital of less ionization potential tends
to be more ionized. Thus HOMO is usually expected to be the most dominant portion in the total ionization probability. However, the ionization process is also related to the molecular orbital symmetry [67, 147, 183]. When the linearly-polarized laser field is applied to the z-axis (parallel, $\Theta=0^\circ$), HOMO and HOMO–2 can be more perturbed and ionized than other orbitals because the induced dipole change of $\sigma$-symmetry is preferable along with this field polarization parallel to the molecular axis [162]. On the other hand, when the field is applied to the x-axis (perpendicular, $\Theta=90^\circ$), HOMO–1 (only $1\pi_{u,x}$ in this case) symmetry is along with the field polarization. Therefore, we expect that the orientation dependence of MPI is reflected by individual orbital symmetries.

In Fig. 3.2, we plot the time-dependent electron population $n_{i\sigma}(t)$ of individual spin-orbitals of N$_2$ in the parallel [Figs. 3.2(a)–(c)] and perpendicular [Figs. 3.2(d)–(f)] cases. We use 20-optical-cycle sin$^2$-envelope laser pulses with the wavelength 800 nm. The peak intensities are $10^{14}$ W/cm$^2$ in Figs. 3.2(a) and (d); $3 \times 10^{14}$ W/cm$^2$ in Figs. 3.2(b) and (e); and $5 \times 10^{14}$ W/cm$^2$ in Figs. 3.2(c) and (f). In the parallel case ($\Theta=0^\circ$), HOMO exhibits the most dominant contribution to the total ionization and HOMO–2 contribution is also increasing as the intensity increases. On the other hand, HOMO–1 contribution is increasing as the intensity increases in the perpendicular case ($\Theta=90^\circ$) due to the orbital symmetry of $\pi_u$. Note that HOMO contribution is still dominant in both cases.

Figure 3.3 shows the orientation dependence of ionization probabilities of N$_2$ with 800 nm and $2 \times 10^{14}$ W/cm$^2$ as a function of the field–molecule orientation angle. Note that larger angular grids are used ($l_{\text{max}}=15$) in calculations to plot individual orbital ionization probabilities in Fig. 3.3 because of a possible resonance between HOMO and HOMO–1. The total ionization
Figure 3.2: Plots of the time-dependent electron population $N_{i\sigma}(t)$ of individual spin-orbitals of N$_2$. The laser peak intensities are $10^{14}$ W/cm$^2$ in (a) and (d), $3 \times 10^{14}$ W/cm$^2$ in (b) and (e), and $5 \times 10^{14}$ W/cm$^2$ in (c) and (f). The field–molecule orientation angles are $\Theta=0^\circ$ for (a)–(c) and $\Theta=90^\circ$ for (d)–(f). The legend in (d) is for all plots.
probability in the polar plot (left panel) looks like a dumbbell shape in accord with experiments [164]. The ionization probabilities of individual orbitals (right panel) illustrates importance of multielectron effects between HOMO and HOMO−1. For Θ=15–40°, HOMO−1 contribution is larger than HOMO contribution. Thus, both HOMO and HOMO−1 contribute to this dumbbell shape of the orientation dependent plot of the total ionization probability. These comparable contributions from HOMO and HOMO−1 are explained by a small orbital energy difference and a strong coupling between HOMO and HOMO−1. In Table 3.1, calculated difference between HOMO and HOMO−1 is only 1.5 eV, which is relatively small in comparison with other molecules in Tables 2.6 and 2.7. Moreover, this energy gap is very close to the photon energy (1.55 eV) corresponding to the carrier wavelength of 800 nm. A transition between HOMO (3σ_g) and HOMO−1 (1π_u) is forbidden in the parallel case (Θ=0°) but allowed in other angles, so it leads to a possible one-photon resonance between HOMO and HOMO−1. This phenomenon is also theoretically predicted in MPI and HHG of N_2 in the 800 nm laser field [184].

Next, we consider effects of laser intensity on the orientation dependent patterns in Fig. 3.4. The peak intensity of laser pulses is varying from 10^{14} to 5 \times 10^{14} W/cm^2, and the wavelength is fixed at 800 nm. All data sets are normalized to their maximum value. As the intensity increases, the polar plot becomes less anisotropic [147] because at higher intensity all orbitals participate in the ionization process, thus losing a characteristic pattern of each orbital.
Figure 3.3: Orientation dependence of total ionization probability (left panel) and individual ionization probability of multiple orbitals (right panel) of N₂ with 800 nm and $2 \times 10^{14}$ W/cm².

Figure 3.4: Effects of laser intensity on the orientation dependence of total ionization probability of N₂.
3.5 Orientation dependence of multiphoton ionization of H$_2$O

We perform TDDFT calculations of H$_2$O with arbitrary field–molecule orientation by means of the TDVFD method. The ground-state electronic configuration of H$_2$O is

$$[\text{core}] (2a_1)^2 (1b_2)^2 (3a_1)^2 (1b_1)^2,$$

where $[\text{core}]$ is $(1a_1)^2$ that corresponds to O 1$s$ orbital. All orbitals except the core orbital participate in the time-propagation. Table 3.2 lists LB$\alpha$ orbital binding energies with a small number of grids in comparison with experiments [148, 152] and $\alpha=1.21$ is used to compensate for inaccuracy in orbital energies. The grid parameters are $N_r=80$, $L=2$ a.u., $r_{\text{max}}=40$ a.u., and $l_{\text{max}}=10$ with the Womersley grids, which provide $N_{\text{total}}=20,022$ for the triatomic H$_2$O molecule. For the time-propagation with $N_{\text{total}}=20,022$ and 20,000 time iterations, the computation time is about 9 hours on the same workstation mentioned in Section 3.4.

Figure 3.5 depicts orbital pictures of H$_2$O with the molecular geometry. The principal axis is the $z$-axis and the molecular geometry is fixed. All atoms of H$_2$O are contained in the $yz$-plane. HOMO (1$b_1$), HOMO–1 (3$a_1$), and HOMO–2 (1$b_2$) have atomic $p$-orbital-like characters along with the $x$-, $z$-, and

Figure 3.5: Molecular geometry and molecular orbital pictures of \( \text{H}_2\text{O} \). The principal axis is the \( z \)-axis and the molecular geometry is fixed. An oxygen atom (red ball) and two hydrogen atoms (white ball) are contained in the \( yz \)-plane. The field polarization axis with respect to the principal axis changes toward the \( x \)-axis (\( \Theta_1 \)) or the \( y \)-axis (\( \Theta_2 \)).

\( y \)-axis, respectively. With respect to the fixed molecular frame of \( \text{H}_2\text{O} \), the field polarization direction can change in two different ways as shown in Fig. 3.5(a). First, the angle changes from the \( z \)-axis toward the \( x \)-axis (denoted by \( \Theta_1 \)). The interaction between the electron and the field is given by

\[
\mathbf{F}(t) \cdot \mathbf{r} = \mathbf{F}(t)(x \sin \Theta_1 + z \cos \Theta_1).
\]  \hspace{1cm} (3.30)

Second, the angle changes from the \( z \)-axis toward the \( y \)-axis (denoted by \( \Theta_2 \)). Then,

\[
\mathbf{F}(t) \cdot \mathbf{r} = \mathbf{F}(t)(y \sin \Theta_2 + z \cos \Theta_2).
\]  \hspace{1cm} (3.31)

According to orbital pictures in Figs. 3.5(b)–(d), there is no orientation dependence when the field polarization varies within the nodal plane of each orbital, while the orientation dependence maximizes when the field polarization approaches the \( p \)-orbital-like polarization of each orbital. In other words, incre-
ment of $\Theta_1$ triggers to maximize HOMO ionization, to minimize HOMO–1 ionization, and no effects on HOMO–2 ionization. On the other hand, increment of $\Theta_2$ causes no effects on HOMO ionization, to minimize HOMO–1 ionization, and to maximize HOMO–2 ionization. Consequently, it provides feasibility to selectively probe the MPI processes of individual orbitals in aligned H$_2$O.

Figure 3.6 shows the orientation dependence of total ionization probability of H$_2$O with 800 nm and $5 \times 10^{13}$ W/cm$^2$ as a function of (a) $\Theta_1$ and (b) $\Theta_2$. The pulse shape is sin$^2$-envelope with the 20-o.c. pulse length. When $\Theta_1$ changes, the orientation dependence of total ionization probability mostly follows the pattern of HOMO as shown in Fig. 3.6(a). On the other side, the appearance of the orientation dependence is dramatically changed when $\Theta_2$ changes. Since HOMO has the nodal plane of the $yz$-plane, the change of $\Theta_2$ in the $yz$-plane does not affect HOMO ionization. Thus the overall pattern of the orientation dependence of total ionization probability is dominantly determined by HOMO–1 as shown in Fig. 3.6(b). To our knowledge, this is the first prediction of the dominant contribution from HOMO–1 to the overall orientation dependent pattern of MPI.

3.6 Orientation dependence of multiphoton ionization of CO$_2$

We perform TDDFT calculations of CO$_2$ with arbitrary field–molecule orientation by means of the TDVFD method. The ground-state electronic configuration of CO$_2$ is

$$[\text{core}](3\sigma_g)^2(2\sigma_u)^2(4\sigma_g)^2(3\sigma_u)^2(1\pi_u)^4(1\pi_u)^4.$$

where [core] indicates 1s orbitals of C and two O’s. All orbitals except the core orbital participate in the time-propagation. Table 3.3 compares experimental vertical ionization potentials [148, 150, 151] of CO$_2$ and absolute values of orbital binding energies computed with LB$_\alpha$. We use $\alpha=1.16$ for the LB$_\alpha$ parameter. The grid parameters are the same as ones used in the H$_2$O calculations in Section 3.5.

Figure 3.7 is a molecular orbital diagram for CO$_2$ showing how to construct CO$_2$ molecular orbitals from atomic orbitals of one C atom and two O atoms in the molecular orbital theory [185], based on experimental energy levels and GAMESS calculations [132]. HOMO ($1\pi_g$) is a non-bonding character and mainly constructed from two O 2$p_x$ orbitals with opposite phases, so it can be approximated by

$$
\psi_{\text{HOMO}} \approx \phi_{O_A 2p_x} - \phi_{O_B 2p_x},
$$

(3.32)
where $O_A$ and $O_B$ indicate the oxygen atom in the left- and right-hand side of the carbon atom. Thus HOMO of $\text{CO}_2$ is the antisymmetric combination with respect to the phase of two atomic $p$ orbitals.

Figure 3.8 displays orbital pictures of $\text{CO}_2$ with the molecular geometry. The molecular axis coincides with the $z$-axis and the field polarization lies in the $xz$-plane. Since $\text{CO}_2$ is a linear molecule, the orientation angle $\Theta$ is defined in the same way as $\text{N}_2$ in Eq. (3.27). Note that the $z$-axis direction is rotated from one in Figs. 3.1 and 3.5 for better representation.

Figure 3.9 shows the orientation dependence of the total ionization probability calculated by Eq. (3.22) as a function of $\Theta$. We used the 20-optical-cycle $\sin^2$-envelope laser pulses with two different sets of the wavelength and the peak intensity: (a) 820 nm and $1.1 \times 10^{14}$ W/cm$^2$, and (b) 800 nm and $5 \times 10^{13}$ W/cm$^2$. For comparison, Fig. 3.9 includes experimental measurements of Pavičić et al. [164] and Thomann et al. [165], and MO–ADK results [164, 186] with corresponding wavelength and peak intensity. All data sets are normal-
Figure 3.8: Molecular geometry and molecular orbital pictures of CO$_2$. The principal axis is the z-axis and the molecular geometry is fixed. One carbon atom (black ball) and two oxygen atoms (red ball) are located in the z-axis. The field polarization axis with respect to the principal axis changes toward the x-axis ($\Theta$).

---

Pavičić et al. [164]; Thomann et al. [165]; Le et al. [186].
ized to their maximum value. In Fig. 3.9(a), two dashed lines of experiment are due to uncertainty of the measured alignment distribution [164]. The total ionization probability computed from TDDFT manifests the center-fat propeller shape with the maximum peak at 40°, which agrees well with both experimental data of 45°-peak [164, 165]. As for the broadness of the central pattern, our results are in good agreement with the data of Thomann et al. [165] but different from the data of Pavičić et al. [164], the latter showing a narrower pattern. The cause of this discrepancy is unknown but might be related to the experimental uncertainty in the molecular alignment processes. On the other side, the MO–ADK model predicts the 25°-peak butterfly shape for both cases [164, 186]. We note that the strong-field approximation model predicts that the peak maximum occurs at 37° [187] and a recent simulation of the time-dependent Schrödinger equation within the single-active electron approximation predicts a 45°-peak [188].

We now examine contributions of individual orbitals on the total ionization probability. The total ionization probability in Eq. (3.22) can be approximately reduced to the summation of those individual probabilities in the limit of small $P_{i\sigma}(T)$, i.e., $P \approx \sum_{i\sigma} P_{i\sigma}(T)$. Figure 3.10 contains individual ionization probabilities $P_{i\sigma}(T)$ of multiple orbitals with 820 nm and $1.1 \times 10^{14}$ W/cm$^2$. HOMO ($1\pi_g$) is dominant in the total ionization and others ($1\pi_u$, $3\sigma_u$, and $4\sigma_g$) are scaled by ten times. Contributions of $2\sigma_u$ and $3\sigma_g$ are negligible. In fact, the unperturbed $\pi$ orbitals are degenerate: one lies on the $xz$-plane ($1\pi_{g,x}$ and $1\pi_{u,x}$) and the other lies on the $yz$-plane ($1\pi_{g,y}$ and $1\pi_{u,y}$). As the field whose polarization vector varies in the $xz$-plane is applied to the molecule, $1\pi_{g,x}$ provides the most dominant contribution to the orientation dependence of the total ionization probability, which has the 45°-peak maximum. $1\pi_{g,y}$ shows a dumbbell
Figure 3.10: Orientation dependence of individual ionization probability of multiple orbitals with 820 nm and $1.1 \times 10^{14}$ W/cm$^2$.

shape with the same probability as $1\pi_{g,x}$ at $\Theta = 0^\circ$. Thus, the center-fat propeller shape of the total ionization probability in Fig. 3.9 is mostly reflected by contributions of two HOMOs ($1\pi_{g,x}$ and $1\pi_{g,y}$).

This prediction is particularly different from the MO–ADK butterfly pattern based on the structure and symmetry of the ground state of HOMO [186, 189]. In MO–ADK, it is understood that the peak angle for CO$_2$ becomes lower than for O$_2$, despite their same HOMO symmetry, because the internuclear distance between two O’s in CO$_2$ ($d=4.392$ a.u.) is longer than in O$_2$ ($d=2.287$ a.u.) [189]. In contrast, our TDDFT results incorporating multielectron effects reveal that the orientation dependence of the ionization probability of HOMO peaks at 45°, similar to the predicted pattern for O$_2$ and F$_2$ that have the same HOMO symmetry [147]. Our all-electron TDDFT study demonstrates the importance of including the electron correlation and all the valence orbitals in the study of strong-field ionization mechanism, even when HOMO is dominant in the ionization process.
Next, we consider effects of laser intensity on the orientation dependent patterns in Fig. 3.11. The peak intensity of laser pulses is varying from $5 \times 10^{13}$ to $3 \times 10^{14}$ W/cm$^2$, and the wavelength is fixed at 800 nm. All data sets are normalized to their maximum value. As the intensity increases, the polar plot becomes less anisotropic as we observed in the N$_2$ case in Section 3.4.

### 3.7 Photoelectron angular distribution of aligned CO$_2$

To explore the orientation dependence of MPI and its relation to molecular orbital symmetry further, we examine the photoelectron angular distribution (PAD) to visualize where the electron is ionized in the strong field as the field–molecule orientation changes. From the flux analysis of the TDDFT solutions, we can retrieve the information of where the density flows in and out. Then we define an alternative ionization probability and its angular differential form for the complete PAD picture.
From the continuity equation, one can compute the ionization probability rate at time $t$,

$$
\dot{P}_{i\sigma}(t) = -\frac{\partial}{\partial t} \int_V \rho_{i\sigma}(r, t) dV = \int_V \nabla \cdot j_{i\sigma}(r, t) dV,
$$

(3.33)

where $\rho_{i\sigma}$ is the spin-orbital density, $\rho_{i\sigma}(r, t) = \psi_{i\sigma}^*(r, t) \psi_{i\sigma}(r, t)$, and $j_{i\sigma}$ is its current density,

$$
j_{i\sigma}(r, t) = \frac{1}{2i} \left[ \psi_{i\sigma}^*(r, t) \nabla \psi_{i\sigma}(r, t) - \psi_{i\sigma}(r, t) \nabla \psi_{i\sigma}^*(r, t) \right]
$$

(3.34)

From the Gauss’ theorem, Eq. (3.33) yields to

$$
\dot{P}_{i\sigma}(t) = \int_V \nabla \cdot j_{i\sigma}(r, t) dV = \int_S j_{i\sigma}(r, t) \cdot n dS.
$$

(3.35)

In general, $V$ is given by the spherical volume and $S$ is the spherical surface with a large-distance boundary radius. The normal component of the current density on the spherical surface is

$$
j_{i\sigma}(r, t) \cdot n = \text{Im} \left[ \psi_{i\sigma}^*(r, t) \frac{\partial}{\partial r} \psi_{i\sigma}(r, t) \right].
$$

(3.36)

Then the time-dependent photoelectron angular distribution is given by

$$
\frac{\partial \dot{P}_{i\sigma}(t)}{\partial \Omega} = r_b^2 \text{Im} \left[ \psi_{i\sigma}^*(r, t) \frac{\partial}{\partial r} \psi_{i\sigma}(r, t) \right]_{r=r_b}.
$$

(3.37)

This expression indicates the rate of the spin-orbital density flowing in and out at time $t$ and at boundary radius $r_b$ that is be chosen to be less than the absorber position $r_0$ in Eq. (3.29). If the right-hand side of Eq. (3.37) $> 0$, the electron
density is flowing out of the sphere of the radius $r_b$. If the right-hand side of Eq. (3.37) $< 0$, the electron density is flowing into the sphere.

After one pulse ($t=T$) where $T$ is a pulse duration, one can define the angular differential ionization probability (ADIP) by integrating Eq. (3.37) over $t$,

$$\frac{\partial P_{i\sigma}}{\partial \Omega} = \int_0^T \frac{\partial P_{i\sigma}(t)}{\partial \Omega} dt = \int_0^T \frac{1}{r_b^2} \text{Im} \left[ \psi_{i\sigma}^*(r, t) \frac{\partial}{\partial r} \psi_{i\sigma}(r, t) \right]_{r=r_b} dt. \quad (3.38)$$

Note that in TDVFD calculations the normal component of the current density in Eq. (3.38) is directly calculated by the VFD gradient of the wavefunction and the inner product, $\{ \text{Im} \left[ \psi_{i\sigma}^*(r, t) \nabla \psi_{i\sigma}(r, t) \cdot n \right] \}$, rather than Eq. (3.38) involving $\partial/\partial r$. Any quantity at $r_b$ is evaluated by the VFD interpolation that is simply given by the value of the Voronoi cell encapsulating a given position. The temporal integral is computed over equal-spaced temporal grids. Then the total ADIP is calculated in the same way as in Eq. (3.22),

$$\frac{\partial P}{\partial \Omega} = 1 - \prod_{i\sigma} \left( 1 - \frac{\partial P_{i\sigma}}{\partial \Omega} \right). \quad (3.39)$$

Based on this density flux analysis, we can alternatively define the total ionization probability. From Eqs. (3.38) and (3.39), the total ionization probability can be computed by integrating over angles,

$$P_{\text{alt}} = \int_0^{2\pi} \int_0^{\pi} \frac{\partial P}{\partial \Omega} \sin \theta \, d\theta \, d\phi, \quad (3.40)$$
<table>

which is comparable with the conventional definition in Eqs. (3.18)–(3.22) based on the norm of the wavefunction,

$$P_{\text{conv}} = 1 - \prod_{i\sigma} \langle \psi_{i\sigma}(\mathbf{r}, T) | \psi_{i\sigma}(\mathbf{r}, T) \rangle.$$ (3.41)

Table 3.4 compares the total ionization probabilities of CO$_2$ computed by two different definitions, $P_{\text{conv}}$ and $P_{\text{alt}}$, at several orientation angles. The wavelength is 820 nm and the peak intensity is $1.1 \times 10^{14}$ W/cm$^2$, and other parameters are the same ones used in Fig. 3.9(a). This comparison confirms that the alternative definition by the flux analysis can correctly represent the ionization probability as the conventional one by the norm analysis. Moreover, the alternative ionization probability is more robust than the conventional one because it can resolve angular distribution of the ionization probability.

Now we examine the total ADIP, which is the angular-resolved total ionization probability for the complete PAD picture. Figure 3.12 displays PAD of CO$_2$ at several field–molecule orientation angles from $\Theta=0^\circ$ to $\Theta=90^\circ$, showing a topological transform from a donut shape to a dumbbell shape. Laser param-
eters are the same ones used in Fig. 3.9(a), and 256 angular grids ($l_{\text{max}}=15$) are used for each atom to get higher angular resolution. The orientation dependence of MPI has the maximum peak at $\Theta=40^\circ$, so other angles except $\Theta=45^\circ$ are scaled by some factors for better representation. The top and middle panels show contour maps of $\partial P/\partial \Omega$ as a function of $\Omega$ on the unit sphere in 3D. In Fig. 3.12, the PAD contour maps exhibit characteristic features of the perturbed HOMO symmetry, because HOMO dominantly contributes to the total ionization. At $\Theta=0^\circ$, PAD forms the donut shape with a nodal point at the center, which is equally from two HOMOs ($1\pi_{g,x}$ and $1\pi_{g,y}$), indicating the retained axial symmetry and degeneracy. At $\Theta=90^\circ$, PAD forms the dumbbell shape with a nodal plane, which is mostly from one HOMO ($1\pi_{g,x}$). Because of the nodal spot and plane at the field polarization axis, the total ionization is suppressed at these orientation angles. On the other hand, PAD at $\Theta=45^\circ$ shows a peak spot coincided with the field polarization axis, thus enhancing the total ionization in this direction. It strongly supports the maximum peak of the orientation dependence near this angle.

To closely observe PAD with respect to the field polarization axis, the polar angle $\theta$ and the azimuth angle $\phi$ are defined with respect to the field polarization axis, and then the polar plot as a function of $\theta$ is obtained by $\partial P/\partial \theta = \int_0^{2\pi} (\partial P/\partial \Omega) d\phi$. The bottom panels in Fig. 3.12 represent $\partial P/\partial \theta$ at corresponding orientation angles. These plots are comparable with conventional PAD 2D polar plots [167, 190]. Our results indicate the significant advantage of using the 3D PAD visualization, since it provides new dynamical information not realizable by the conventional 2D polar plot. For example, while the patterns of the bottom panels at $\Theta=0^\circ$ and $\Theta=90^\circ$ look alike, the corresponding 3D patterns are completely different.
Figure 3.12: 3D contour maps of photoelectron angular distribution at several orientation angles. The top panels display contour maps of $\partial P / \partial \Omega$ on the unit sphere with a vertical line of the molecular axis and an arrow line of the field polarization axis. The middle panels show the same spherical contour maps in different views that the field polarization axis is perpendicular to the paper. The bottom panels represent polar plots of $\partial P / \partial \theta$ with a horizontal arrow line of the field polarization axis.
3.8 High-order harmonic generation of aligned CO$_2$

We perform HHG calculations for CO$_2$ with arbitrary field–molecule orientation by means of TDDFT and TDVFD. Figure 3.13 shows the HHG spectrum $S(\omega)$ for CO$_2$ with the wavelength 800 nm and the peak intensity $1 \times 10^{14}$ W/cm$^2$ at two orientation angles $\Theta=0^\circ$ and $\Theta=90^\circ$. Other laser parameters are the same as ones used in Section 3.6. Since the HHG calculations require very accurate wavefunctions especially for the long range, the high-order scheme would be preferable. However, the high-order VFD scheme currently described in Section 2.7 has a few drawbacks to be extended for TDDFT calculations. For this reason, we use the first-order VFD method with a large number of grid points for the HHG calculations. We found that the Lebedev scheme for angular grids is suitable for the HHG calculations because its intrinsic symmetry property provides more accurate results for dipole moment calculations. Also a larger mapping parameter $L$ for radial grids is more desirable to achieve better accuracy for higher harmonics. But too large $L$ yields inaccurate core orbitals, thus resulting a collapse of wavefunctions after a few optical cycle of the time propagation. Therefore, $L=4–5$ a.u. is appropriately recommended with $N_r=100$ and more for the HHG calculations. In the present calculations, we use $N_r=100$, $L=5$ a.u., $r_{\text{max}}=40$ a.u., and $l_{\text{max}}=10$ with the Lebedev grids.

According to the semiclassical model [191, 192], the HHG spectra has a plateau ending at the cut-off energy estimated by $I_p + 3.17U_p$ where $I_p$ is the ionization potential and $U_p$ is the ponderomotive energy that is given by $U_p = E^2/4\omega^2$ where $E$ is the field strength and $\omega$ is the field frequency. For the system and field parameters used in our calculations, the cut-off position from the model, $(I_p + 3.17U_p)/\omega$, is expected to be around 21st harmonic order, which
is in fair agreement with our computed data as shown in Fig. 3.13. Molecular HHG spectra demonstrate another hump after the cut-off position, which has been debated regarding to multiple orbital contributions [173]. Also HHG spectra of N₂ and F₂ and its orientation dependence are explained by the multi-electron effects such as interferences among multiple orbital contributions and a resonance between adjacent molecular orbitals [184].

Next we explore the field–molecule orientation dependence of CO₂ HHG. HHG mechanism is well explained by the following three stages [191, 193]: i) an electron is detached from atoms or molecules by multiphoton or tunneling ionization; ii) the electron goes away and comes back influenced by the oscillating field, acquiring a kinetic energy; and iii) a harmonic photon is emitted when the returning electron recombines with the parent core. According to this three-step model, the orientation dependence of HHG can be reflected by two factors: the ionization process and the recombination process. First, the har-
monic generation is enhanced when the ionization probability is maximized and suppressed when it is minimized. Second, quantum interference among different centers may occur in the recombination process. Especially for the diatomic molecules, there are two centers in the parent core, so that two different pathways in recombination lead to quantum interference, which is simply formulated in the two-center interference model [194, 195]. If we assume that all the return kinetic energy of the electron is converted into the harmonic energy, we have the following condition for the interference minima or maxima in the orientation dependence of the harmonic spectra,

\[ \cos \Theta = \frac{\pi}{R \sqrt{2n\omega}}, \tag{3.42} \]

where \( \Theta \) is the orientation angle, \( R \) is the distance between two centers, \( n \) is the harmonic order, and \( \omega \) is the incident field frequency. If the molecular orbital responsible for the harmonic emission mechanism is the symmetric combination of atomic orbitals, i.e., the phases of two-center emitters are the same, the condition in Eq. (3.42) gives the minima due to destructive interference. On the other hand, if the molecular orbital is the antisymmetric combination (the opposite phases), Eq. (3.42) yields the maxima due to constructive interference. Even though CO\textsubscript{2} is not a diatomic molecule, it is also subject to the two-center interference model because HOMO of CO\textsubscript{2} is mainly constructed from two atomic \( p \) orbitals of oxygen. Indeed, CO\textsubscript{2} has been widely investigated as a testbed for the two-center interference model [161, 196, 197]. HOMO of CO\textsubscript{2} is the antisymmetric combination in Eq. (3.32), so we expect the maximum positions in the orientation dependence.
Figure 3.14: Harmonic spectra of CO$_2$ as a function of the harmonic order and the orientation angle with 800 nm and $1 \times 10^{14}$ W/cm$^2$.

Figure 3.14 shows harmonic spectra of CO$_2$ as a function of the harmonic order $n$ and the orientation angle $\Theta$. Laser parameters are the same as ones used in Fig. 3.13. Overall pattern is that the harmonic spectra have the minimum around $\Theta=0^\circ$ and $\Theta=90^\circ$ due to the suppression of the ionization process at this angle. Also the harmonic spectra have the maximum around $\Theta=50–70^\circ$ for near the cut-off position ($n=15–23$), rather than around $\Theta=40^\circ$ that is the peak angle in the ionization probability as we have seen in Section 3.6. These maximum positions may be explained by the two-center interference. The present harmonic spectra of CO$_2$ in Fig. 3.14 are in fair agreement with a recent experimental and theoretical results [173].

To see the two-center interference effect in detail, we plot normalized harmonic spectra as a function of $\Theta$ for a few harmonics in Fig. 3.15. All data are normalized to the maximum value for each harmonic. As one can see clearly,
Figure 3.15: Normalized harmonic spectra of CO$_2$ as a function of the orientation angle with 800 nm and $1 \times 10^{14}$ W/cm$^2$.

Table 3.5: Orientation angles of the interference maxima for several harmonics in the HHG spectra of CO$_2$ with 800 nm and $1 \times 10^{14}$ W/cm$^2$.

there are the maximum positions in the orientation dependence of the harmonic spectra. In Table 3.5, we compare orientation angles of the interference maxima for several harmonics in the HHG spectra of CO$_2$, computed by our TDDFT results and the two-center interference model in Eq. (3.42). $d=4.392$ a.u. is given by the distance between two oxygen atoms. For the harmonic orders less than the cut-off, the maximum positions predicted by the model are in fair agreement with our TDDFT calculations, but agreement is not good after the cut-off position ($n \geq 21$). Also it might be responsible for this disagreement that the simple semiclassical model is not justifiable for weaker intensity [67].
Chapter 4

Many-mode Floquet approach for the study of coherent control of multiphoton processes in frequency-comb laser fields

We extend the many-mode Floquet theorem (MMFT) for the investigation of multiphoton resonance dynamics driven by intense frequency-comb laser fields. The frequency comb structure generated by a train of short laser pulses can be exactly represented by a combination of the main frequency and the repetition frequency. MMFT allows non-perturbative and exact treatment of the interaction of a quantum system with the frequency-comb laser fields. We observe simultaneous multiphoton resonance processes between a two-level system and frequency-comb laser. The multiphoton processes can be coherently controlled by tuning the laser parameters such as the carrier-envelope phase (CEP) shift. High-order harmonic generation (HHG) driven by intense frequency-comb laser has a nested comb structure with the same repetition frequency and different offset for each harmonic. Moreover, HHG driven by intense frequency-comb laser shows immense enhancement by tuning the CEP
shift due to simultaneous multiphoton resonance among all the comb frequencies.

### 4.1 Frequency-comb laser fields

Frequency-comb laser generated from the mode-locked short-pulse laser has been leading advances in high-precision spectroscopy and ultrafast science [198, 199]. Recent progress of mode-locked laser has allowed to stabilize optical frequency combs by precise control of the absolute comb position and comb spacing [199, 200, 201, 202]. The frequency-comb laser technology has remarkably impacted on high-precision optical frequency measurement and synthesis [203, 204, 205, 206], optical atomic clock [198, 207, 208], as well as high sensitive molecular detection [209, 210].

More recently, the feasibility of the extension of the frequency comb structure and coherence into vuv–xuv regimes via HHG has attracted considerable attention [211, 212, 213, 214]. It is speculated that the frequency comb structure may be retained in each of the higher harmonics. However, currently the experimental realization of the comb structure in higher harmonics has not yet been achieved due to some experimental resolution problems, with the exception of the third harmonic [212] and the 7–13th harmonics [215]. It is also not clear whether the frequency comb structure and coherence can survive in very high-order harmonics and in the situation where substantial ionization occurs in the presence of high intensity laser fields. To advance this field, we have recently presented \textit{ab initio} theoretical exploration of the frequency comb structure and coherence in the vuv–xuv regimes via HHG from the hydrogen atom by propagating the time-dependent Schrödinger equation [55] and from the he-
lithium atom by using time-dependent density-functional theory [216]. We found that each harmonic (from the first harmonic all the way to the cutoff) has a nested comb structure and this global pattern persists regardless of the time interval and the number of pulses, even in the presence of appreciable ionization. We also showed that the comb structure of the harmonics originates from quantum interferences among induced dipole moment pulses by use of the spectral phase analysis [55].

4.2 Field expressions in the time and frequency domains

We derive field expressions of frequency-comb laser in the frequency domain and in the time domain, and then make an explicit connection between them to be suitable for the Floquet formalism in Section 4.3. Basically, frequency-comb laser consists of spectral comb lines in the frequency domain [199, 201],

$$\omega_m = m\omega_r + \omega_\delta$$

(4.1)

where \(\omega_r\) is the repetition angular frequency, \(m\) is an integer index, and \(\omega_\delta\) is the offset angular frequency \((0 \leq \omega_\delta < \omega_r)\). This frequency-comb laser can be generated by a temporal train of short laser pulses which have the carrier (fundamental) angular frequency \(\omega_c\) and the time interval \(\tau\) between pulses. Because the time period \((=2\pi/\omega_c)\) of the carrier wave and the time duration \(\tau(=2\pi/\omega_r)\) of the pulse envelope are often incommensurate, there is the carrier-envelope phase (CEP) after each pulse: \(\phi = \omega_c \tau\). Current mode-locking laser technique allows us to precisely control the CEP by including the pulse-to-pulse CEP shift \(\Delta\phi\) that plays a key role in stabilizing of the comb structure [200]. The CEP shift
$\Delta \phi$ determines all absolute positions of frequencies in the comb structure by setting the offset frequency $\omega_\delta = \Delta \phi / \tau$.

The electric field for a train of pulses with the CEP shift in the time domain [201] is expressed by

$$E(t) = \sum_{n=1}^{N_p} f(t - n\tau) e^{i(\omega_c t - n\omega_c \tau + n\Delta \phi)}, \quad (4.2)$$

where $N_p$ is the number of pulses and $f(t)$ is the envelope function for one pulse in the time domain. After the Fourier transform, the electric field in the frequency domain [201] is given by

$$\tilde{E}(\omega) = \tilde{f}(\omega - \omega_c) \sum_{n=1}^{N_p} e^{-i n (\omega \tau - \Delta \phi)}, \quad (4.3)$$

where $\tilde{f}(\omega) = \int f(t) e^{-i \omega t} dt$ determines the field strength in the spectrum as the envelope function in the frequency domain. The summation of the exponentials generates frequency comb structure because they are added up with constructive interferences only at $\omega \tau - \Delta \phi = 2\pi m$ with an arbitrary integer $m$ [200]. In other words, the summation becomes a series of frequency lines at $\omega = \omega_m$ such that

$$\omega_m = \frac{2\pi m}{\tau} + \frac{\Delta \phi}{\tau} = m\omega_r + \omega_\delta, \quad (4.4)$$

which is shown as the comb frequency expression in Eq. (4.1). Without loss of generality, we can rewrite these comb frequencies with a main angular frequency $\omega_0$,

$$\omega_k = \omega_0 + k\omega_r, \quad (4.5)$$
where \( k \) is an integer index and \( \omega_0 \) is the main angular frequency defined to be the frequency in \( \{ \omega_m \} \) whose field amplitude is the maximum in the frequency domain. In other words, \( \omega_0 \) is the closest frequency to \( \omega_c \) among all the comb frequencies. The relation between \( \omega_0 \) and \( \omega_c \) is given by

\[
\omega_0 = \left[ \frac{\omega_c - \omega_\delta}{\omega_r} \right] \omega_r + \omega_\delta, \tag{4.6}
\]

where \[ \] is the round function. Note that the fundamental frequency \( \omega_c \) is not necessarily one of the comb frequencies nor does it equal \( \omega_0 \) in general. But if we choose \( \omega_c = \omega_0 \) or \( \omega_c \in \{ \omega_k \} \), then \( \omega_\delta \) will be a reminder of \( \omega_c \) divided by \( \omega_r \).

When the number of pulses increases, the spectral width of each frequency comb becomes narrower due to quantum interference [55, 205]. In the ideal case that an infinite number of pulses are added up, the summation part in Eq. (4.3) yields a series of delta functions centered at each \( \omega_k \),

\[
\lim_{N_p \to \infty} \sum_{n=1}^{N_p} e^{-in(\omega \tau - \Delta \phi)} = \frac{2\pi}{\tau} \sum_{k=\infty}^{\infty} \delta(\omega - \omega_k). \tag{4.7}
\]

Thus, the ideal comb laser field in the frequency domain can be represented by

\[
\tilde{E}^\circ(\omega) = \tilde{f}(\omega - \omega_c)\omega_r \sum_{k=\infty}^{\infty} \delta(\omega - \omega_k), \tag{4.8}
\]

where \( ^\circ \) denotes the ideal case. After applying the inverse Fourier transform to \( \tilde{E}^\circ(\omega) \), we obtain a time-domain expression for the electric field of the ideal
comb laser,

$$E^0(t) = \frac{\omega_r}{2\pi} \sum_{k=-\infty}^{\infty} \int_{-\infty}^{\infty} \delta(\omega - \omega_k) \tilde{f}(\omega - \omega_c) e^{i\omega t} d\omega = \sum_{k=-\infty}^{\infty} E_k e^{i\omega_k t}, \quad (4.9)$$

where $E_k = \tilde{f}(\omega_k - \omega_c) \omega_r / 2\pi$ represents the field amplitude of $\omega_k$. This summation of exponentials of the angular frequencies $\{\omega_k\}$ with their field amplitudes $\{E_k\}$ is coherently added up and then generates the ideal comb structure in the frequency domain. Inversely, this expression plots an infinite number of train pulses in the time domain, i.e., Eq. (4.9) is identical to Eq. (4.2) if $N_p$ goes to infinity.

If the envelope function $f(t)$ is given by a Gaussian form, then the infinite summation in Eq. (4.9) will reduce to the finite summation, and the field amplitudes can be explicitly determined. Let $f(t) = f_0 e^{-t^2/2\sigma^2}$ where $f_0$ is the peak field amplitude at $t = 0$ and $\sigma$ is the standard deviation of the Gaussian function. An integer number $N$ is chosen such that $E_k \approx 0$ when $|k| > N$. As a result, the electric field of $(2N + 1)$ comb frequencies is given by

$$E(t) = \sum_{k=-N}^{N} E_k e^{i\omega_k t}, \quad (4.10)$$

where the field amplitude $E_k$ corresponding to $\omega_k$ is explicitly derived as,

$$E_k = \frac{\omega_r}{2\pi} \int_{-\infty}^{\infty} f_0 e^{-t'^2/2\sigma^2} e^{-i(\omega_k - \omega_c)t'} dt' = \frac{f_0 \sigma \omega_r}{\sqrt{2\pi}} e^{-\sigma^2(\omega_0 - \omega_c + k\omega_r)^2/2}. \quad (4.11)$$

Note that the standard deviation $\sigma$ of the Gaussian function is related to full width at half maximum (FWHM = $2\sigma \sqrt{2\ln 2}$).

To investigate the interaction of an atomic or molecular system with the comb laser generated by a finite number of pulses, Eq. (4.2) has been employed
for solving the time-dependent Schrödinger equation in the time domain [55].

On the other hand, for the ideal comb laser generated by an infinite number of pulses, Eq. (4.10) is more preferable to use, but it may require infinite duration time for the time propagation. Consequently, in order to consider the interaction with the ideal comb laser, it is more expedient to avoid the time propagation of wavefunctions.

### 4.3 Many-mode Floquet theoretical treatment for the interaction of a quantum system with frequency-comb laser

The many-mode Floquet theory (MMFT) [28, 217, 218, 219, 220] can be applied to the solution of the polychromatic or quasi-periodic time-dependent Schrödinger equation without the time propagation of wavefunctions. Let us now consider the interaction of an atomic or molecular system with a linearly polarized frequency-comb laser parallel to the $z$-axis. The corresponding Hamiltonian including $(2N + 1)$ comb frequencies is given by,

$$
H(r, t) = \hat{H}_0(r) - \sum_{k=-N}^{N} \mu(r) \cdot E_k \text{Re} \left[ e^{i\omega_k t} \right]
$$

$$
= \hat{H}_0(r) - \sum_{k=-N}^{N} \hat{z}E_k \cos \omega_k t
$$

$$
= \hat{H}_0(r) - \sum_{k=-N}^{N} \frac{1}{2} \hat{z}E_k \left[ e^{i(\omega_0 + k\omega_r)t} + e^{-i(\omega_0 + k\omega_r)t} \right],
$$

where $\hat{H}_0(r)$ is the unperturbed Hamiltonian of the system and $\mu(r)$ is the electric dipole moment operator.

The MMFT states that any polychromatic (multi-color laser-field) problem has the exact solution in terms of the generalized many-mode quasienergy.
eigenvalues and eigenfunctions [28, 217]. Because all the comb frequencies can be represented by two variables, $\omega_0$ and $\omega_r$, we can employ the two-mode Floquet theory with double Fourier components,

$$|\alpha nm\rangle = |\alpha\rangle \otimes |n\rangle \otimes |m\rangle,$$

(4.13)

where $\alpha$ is the system index, and $n$ and $m$ are Fourier components of $\omega_0$ and $\omega_r$, respectively. Then, the Hamiltonian can be expanded with double Fourier components of $n$ and $m$,

$$H(r, t) = \sum_{n,m} H^{[n,m]}(r)e^{-i(n\omega_0 + m\omega_r)t},$$

(4.14)

where

$$H^{[0,0]} = \hat{H}_0,$$

$$H^{[-1,0]} = H^{[+1,0]} = -\frac{1}{2}\hat{E}_0,$$

$$H^{[-1,-1]} = H^{[+1,+1]} = -\frac{1}{2}\hat{E}_1,$$

$$H^{[-1,1]} = H^{[+1,-1]} = -\frac{1}{2}\hat{E}_{-1},$$

(4.15)

$$H^{[-1,-2]} = H^{[+1,+2]} = -\frac{1}{2}\hat{E}_2,$$

$$H^{[-1,2]} = H^{[+1,-2]} = -\frac{1}{2}\hat{E}_{-2},$$

$$\vdots \quad \vdots$$

$$H^{[-1,-N]} = H^{[+1,+N]} = -\frac{1}{2}\hat{E}_N,$$

$$H^{[-1,+N]} = H^{[+1,-N]} = -\frac{1}{2}\hat{E}_{-N}.$$

The MMFT allows the exact transformation of the time-dependent problem into an equivalent time-independent infinite-dimensional generalized Floquet matrix eigenvalue problem,

$$\sum_{\beta} \sum_{n'} \sum_{m'} \langle \alpha nm | H_{F} | \beta n'm' \rangle \langle \beta n'm' | \lambda \rangle = \lambda \langle \alpha nm | \lambda \rangle,$$

(4.16)
where \( \lambda \) is the quasienergy eigenvalue and \( |\lambda \rangle \) is the corresponding eigenvector.

The two-mode Floquet matrix \( H_F \) is constructed by

\[
\langle \alpha nm | H_F | \beta n' m' \rangle = H_{\alpha \beta}^{[n-n',m-m']} + (n \omega_0 + m \omega_r) \delta_{\alpha,\beta} \delta_{n,n'} \delta_{m,m'},
\]

(4.17)

where

\[
H_{\alpha \beta}^{[n-n',m-m']} = \langle \alpha | H^{[n-n',m-m']} | \beta \rangle \\
= \epsilon_{\alpha} \delta_{\alpha,\beta} \delta_{n,n'} \delta_{m,m'} + \sum_{k=-N}^{N} V_{\alpha \beta}^{(k)} (\delta_{n+1,n'} \delta_{m+k,m'} + \delta_{n-1,n'} \delta_{m-k,m'}),
\]

\[
\epsilon_{\alpha} = \langle \alpha | \hat{H}_0 | \alpha \rangle \quad \text{and} \quad V_{\alpha \beta}^{(k)} = -\frac{1}{2} E_k \langle \alpha | \hat{z} | \beta \rangle.
\]

(4.18)

The \( H_F \) matrix has a block band-diagonal structure with infinite-dimensional diagonal blocks and subdiagonal blocks corresponding to interactions between the quantum system and the \((2N + 1)\) comb frequencies. The structure of \( H_F \) for the linearly polarized case is as follows,

\[
H_F = \begin{pmatrix}
\vdots & & & & \\
& A + 2 \omega_r I & B_1 & B_2 & B_3 & B_4 & \cdots \\
& B_1^T & A + \omega_r I & B_1 & B_2 & B_3 & \\
& B_2^T & B_1^T & A & B_1 & B_2 & \\
& B_3^T & B_2^T & B_1^T & A - \omega_r I & B_1 & \\
& \vdots & B_4^T & B_3^T & B_2^T & B_1^T & A - 2 \omega_r I & \vdots
\end{pmatrix},
\]

(4.19)
where $A$ is a block tridiagonal matrix and $B_k$ is a block off-diagonal matrix.

$$A = \begin{pmatrix} \cdots & \cdots & \cdots & \cdots \\ \vdots & \vdots & \vdots & \vdots \\ Z+2\omega_0 I & X & 0 & 0 & 0 & \cdots \\ X & Z+\omega_0 I & X & 0 & 0 \\ 0 & X & Z & X & 0 \\ 0 & 0 & X & Z-\omega_0 I & X \\ \cdots & 0 & 0 & 0 & X & Z-2\omega_0 I \\ \vdots & & & & \vdots & \vdots \end{pmatrix}, \quad (4.20)$$

$$B_k = \begin{pmatrix} \cdots & \cdots & \cdots & \cdots \\ \vdots & \vdots & \vdots & \vdots \\ 0 & Y_k & 0 & 0 & 0 & \cdots \\ Y_{-k} & 0 & Y_k & 0 & 0 \\ 0 & Y_{-k} & 0 & Y_k & 0 \\ \cdots & 0 & 0 & Y_{-k} & 0 \\ \vdots & & & & \vdots & \vdots \end{pmatrix}, \quad (4.21)$$
The matrices of $X$, $Y_k$, and $Z$ which form blocks in $A$ and $B$ have the following forms,

\[
X = \begin{pmatrix}
0 & V_{\alpha\beta}^{(0)} & V_{\alpha\gamma}^{(0)} & \cdots \\
V_{\beta\alpha}^{(0)} & 0 & V_{\beta\gamma}^{(0)} & \cdots \\
V_{\gamma\alpha}^{(0)} & V_{\gamma\beta}^{(0)} & 0 & \cdots \\
\vdots & \vdots & \vdots & \ddots \\
\end{pmatrix},
\]

\[
Y_k = \begin{pmatrix}
0 & V_{\alpha\beta}^{(k)} & V_{\alpha\gamma}^{(k)} & \cdots \\
V_{\beta\alpha}^{(k)} & 0 & V_{\beta\gamma}^{(k)} & \cdots \\
V_{\gamma\alpha}^{(k)} & V_{\gamma\beta}^{(k)} & 0 & \cdots \\
\vdots & \vdots & \vdots & \ddots \\
\end{pmatrix},
\]

\[
Z = \begin{pmatrix}
\varepsilon_\alpha & 0 & 0 & \cdots \\
0 & \varepsilon_\beta & 0 & \cdots \\
0 & 0 & \varepsilon_\gamma & \cdots \\
\vdots & \vdots & \vdots & \ddots \\
\end{pmatrix}.
\] (4.22)

After solving the eigenvalue problem of the generalized Floquet matrix, the time-averaged transition probability can be computed from the quasienergy eigenvectors [217],

\[
\bar{P}_{\alpha \rightarrow \beta} = \sum_{n,m} \sum_{\gamma,n',m'} \left| \langle \beta nm | \lambda_{\gamma n' m'} \rangle \langle \lambda_{\gamma n' m'} | \alpha 00 \rangle \right|^2,
\] (4.23)

which has the maximum value of $\frac{1}{2}$ at avoided crossings of quasienergies associated with multiphoton resonance transitions [218]. The induced dipole moment can be likewise expanded in double Fourier series,

\[
d(t) = \sum_{n,m} d_{n,m} e^{-i(n\omega_0 + m\omega_r)t}.
\] (4.24)
If \( n \) and \( m \) are given, the angular frequency \( \omega \) is determined by \( \omega = n\omega_0 + m\omega_r \).

The HHG power spectra in the length form can be expressed by [45]

\[
P(n\omega_0 + m\omega_r) = |d_{n,m}|^2 = \left| \sum_{n',m'} \langle \lambda_{\beta,n'-n,m'-m}|\hat{z}|\lambda_{\alpha,n',m'} \rangle \right|^2.
\] (4.25)

Here harmonic order is defined by \( \omega / \omega_c \) and can be a fractional number because of the comb structure of frequencies.

### 4.4 Coherent control of multiphoton resonance dynamics of a two-level system

In this section, we present a case study of the multiphoton resonance enhancement of a two-level system driven by frequency-comb laser fields. The laser parameters used are peak intensity \( 2.5 \times 10^{15} \text{ W/cm}^2 \), carrier frequency 563.5 THz (corresponding to \( \omega_c = 0.0856454 \text{ a.u.} \) and wavelength 532 nm), and repetition frequency 10 THz (corresponding to \( \omega_r = 1.51983 \times 10^{-3} \text{ a.u.} \) and pulse separation \( \tau = 0.1 \text{ ps} \)) generated from a train of Gaussian pulses with 20 fs FWHM. The main frequency \( \omega_0 \) is set to be the carrier frequency \( \omega_c \), so that the offset angular frequency \( \omega_\delta \) is chosen to be a reminder of \( \omega_c \) divided by \( \omega_r \). For the two-level system, the transition dipole moment \( \langle \alpha|\hat{z}|\beta \rangle = 0.1 \text{ a.u.} \) is used. Fig. 4.1(a) shows the two-mode quasienergies, and Fig. 4.1(b) shows the time-averaged transition probabilities as a function of energy separation of the two-level system, \( \hbar \omega_{\alpha\beta} = \varepsilon_\beta - \varepsilon_\alpha \), varying from 0.0 to 0.5 a.u. Multiphoton resonances are found near odd numbers of \( \omega_c \) similar to the one-mode Floquet calculation [221]. However, a cluster of resonances are observed in the vicinity of resonance positions due to the comb structure of frequencies. The
Figure 4.1: (a) Quasienergies and (b) time-averaged transition probabilities as a function of the energy separation, for the two-level system driven by frequency-comb laser fields with peak intensity $2.5 \times 10^{15}$ W/cm$^2$, carrier frequency 563.5 THz, and repetition frequency 10 THz of 20 fs FWHM Gaussian pulses. (c) Enlarged quasienergy plots in the one-photon resonance regime corresponding to the gray box in (a). (d) The corresponding time-averaged transition probabilities.
quasi-periodic structure of the quasienergies can be represented by [217, 218],

\[ \lambda_{\gamma nm} = \lambda_{\gamma} + n\omega_0 + m\omega_r, \]  

(4.26)

where \( n \) is an even integer when \( \gamma = \alpha \) and an odd integer when \( \gamma = \beta \) due to parity consideration. Because of multiples of \( \omega_r \), the quasienergy plot becomes more complicated with avoided crossings as shown in Fig. 4.1(c), where the one-photon dominant resonance pattern is enlarged from the gray box in (a). The corresponding transition probabilities are shown in Fig. 4.1(d).

Many features of the frequency-comb structure can be explained by simultaneous multiphoton resonances that occur due to the multitude of frequencies at the same time. Let us consider an \( n \)-photon resonance condition of a monochromatic frequency \( \omega \),

\[ \omega_{\text{res}} = n\omega, \]  

(4.27)

where \( \omega_{\text{res}} \) is the resonance frequency. On the other side, when one comb frequency \( \omega \) is on \( n \)-photon resonance, many combinations of comb frequencies can simultaneously contribute to that multiphoton resonance. For example, if \( \omega_{\text{res}} = n\omega \) where \( \omega \in \{m\omega_r + \omega_\delta\} \), then a combination of \((n-2)\omega\), \(\omega - \omega_r\), and \(\omega + \omega_r\) is also on resonance with \(\omega_{\text{res}}\). Thus, all combinations of \( \omega \) with \( \pm l\omega_r (l: \text{integer}) \) are also contributed to the resonance. Consequently, the \( n \)-photon resonance condition with frequency combs can be expressed by the congruence relation of real numbers,

\[ \omega_{\text{res}} \equiv n\omega \pmod{\omega_r}. \]  

(4.28)
Eq. (4.28) means the reminders of $\omega_{\text{res}}$ and $n\omega$ are the same when divided by $\omega_r$.

Now, we explore the optimization of the multiphoton resonance processes by tuning the CEP shift $\Delta\phi$. We note that changing the CEP shift, the resonance processes can be easily achieved because $\Delta\phi$ determines absolute comb positions more precisely than $\omega_c$ and even $\omega_r$ ($\omega_\delta = \omega_r\Delta\phi/2\pi$). For example, with the laser parameters used in Fig. 4.1, 1% variation on $\Delta\phi$ yields 0.018% changes on frequencies, which emphasizes the control of the CEP shift in comb laser is much easier than the control of the carrier frequency in one-mode (monochromatic) laser to reach the resonance frequency. Also the resonance position will be retained when the phases vary because the pulse energy is conserved. Moreover, when the CEP shift is varied, it is possible to achieve $n$ times of $n$-photon resonance, where $n$ is an odd number. If comb frequencies with the offset $\omega_\delta$ are $n$-photon resonant with $\omega_{\text{res}}$,

$$\omega_{\text{res}} \equiv n(m\omega_r + \omega_\delta) \pmod{\omega_r}$$

$$\equiv n\omega_\delta \pmod{\omega_r}, \quad (4.29)$$

then $\omega_\delta + \frac{j}{n}\omega_r$ ($j$: integer, $0 \leq j < n$) are also $n$-photon resonant with $\omega_{\text{res}}$, leading to simultaneous multiphoton resonances, because

$$n \left( m\omega_r + \omega_\delta + \frac{j}{n}\omega_r \right) \equiv n\omega_\delta \pmod{\omega_r}. \quad (4.30)$$

Eqs. (4.29) and (4.30) show that comb frequencies with $\omega_\delta$ and with $\omega_\delta + \frac{j}{n}\omega_r$ have the same reminder as $\omega_{\text{res}}$ when divided by $\omega_r$. The CEP shifts of comb
Figure 4.2: (a) Quasienergies and (b) time-averaged transition probabilities as a function of the CEP shift $\Delta \phi$. It shows three resonance positions separated by $2\pi/3$ due to three-photon dominant resonance.

frequencies with the offset $\omega_\delta + \frac{j}{n} \omega_r$ are given by

$$\Delta \phi_j = 2\pi \left( \frac{\omega_*}{\omega_r} + \frac{j}{n} \right) \quad (0 \leq j < n), \quad (4.31)$$

so that resonance peak positions of $\Delta \phi_j$ are separated by $2\pi/n$. Fig. 4.2 shows (a) the quasienergies and (b) the time-averaged transition probabilities as a function of the CEP shift. The energy separation is fixed at $\omega_{\alpha\beta} = 0.25$ a.u. which corresponds to the three-photon dominant resonance regime ($3\omega_\epsilon \approx \omega_{\alpha\beta}$), and $\Delta \phi$ is varied ($0 \leq \Delta \phi < 2\pi$). Other laser parameters are the same as those in Fig. 4.1. Shown in Fig. 4.2 is the case of three-photon dominant resonance. Here the resonance can be achieved three times by varying the CEP shift, and these three peaks are separated by $2\pi/3$ exactly.
4.5 Enhancement of high-order harmonic generation

In Fig. 4.3, we present the HHG power spectrum of two-level systems driven by frequency-comb laser. The laser parameters are the same as those in Fig. 4.1 and the energy separation is fixed at \( \omega_{\alpha\beta} = 0.25 \) a.u. For comparison, HHG driven by one-mode laser with the same carrier frequency and the corresponding root-mean-square field strength is plotted with the dots in Fig. 4.3, computed by one-mode Floquet calculation. Note that HHG spectrum driven by comb laser is orders of magnitude higher than that by one-mode laser. In addition, HHG driven by comb laser forms a nested comb structure within each of the harmonics, due to the constructive interferences among the sequence of induced dipoles generated by the incident sequence of laser pulses [55]. For instance, the comb structure within the fifth-order harmonic is shown in the inset in Fig. 4.3. Each of the harmonic orders has the same repetition angular frequency \( \omega_r \) and the offset angular frequency \( n\omega_\delta \) for the \( n \)th-order harmonic. The frequency comb spectrum for the \( n \)th-order harmonic can be expressed with \( \omega_0 \),

\[
\omega'_{k} = n\omega_0 + k\omega_r,
\]

(4.32)

or expressed with \( \omega_\delta \),

\[
\omega'_m = n\omega_\delta + m\omega_r,
\]

(4.33)

where \( m \) and \( k \) are an integer index.

Finally, we investigate the coherent control and enhancement of the HHG power spectra by tuning the CEP shift to achieve multiphoton resonances. Figure 4.4 shows the enhancement of HHG by varying the CEP shift, \( \Delta \phi / 2\pi = 0.1 \) (off-resonance), 0.168, and 0.168295 (near-resonance) with peak intensity \( 1 \times \)
$10^{14}$ W/cm$^2$. Other parameters for comb laser and the system are the same as those in Fig. 4.3. Table 4.1 lists the power spectrum values of the maximum peak for the near- and off-resonance cases with several peak intensities. Figure 4.4 and Table 4.1 show that HHG peaks can be dramatically enhanced by varying the CEP shift due to simultaneous multiphoton resonances. In the case of $n$-photon resonance processes, the system can easily reach the excited state by the absorption of $n$ photons and the higher-order ($>n$) harmonic spectra can be also enhanced. The power spectra of $I=1 \times 10^{14}$ W/cm$^2$ are enhanced by about $10^8$ times. For the case of $I=1 \times 10^{15}$ W/cm$^2$, an enhancement factor is about $10^5$ times, while for the case of $I=2.5 \times 10^{15}$ W/cm$^2$, it is about $10^3$ times. Note that similar enhancement is observed at other resonance positions of the CEP shift. For example, Fig. 4.2(b) indicates three different resonance positions of $\Delta \phi$ at $I=2.5 \times 10^{15}$ W/cm$^2$. The enhancement factors of the HHG power spectrum with $\Delta \phi/2\pi=0.2697$, or $0.2697 + 1/3$, or $0.2697 + 2/3$ are all the same about $10^3$ times.
Figure 4.3: HHG power spectrum of two-level systems driven by frequency-comb laser. Each harmonic has a nested comb structure as clearly shown in the inset for the fifth harmonic. For clarity, all comb peaks are connected by a line. The laser parameters are the same as those in Fig. 4.1. Dots represent HHG spectra driven by the corresponding one-mode laser.

Figure 4.4: Enhancement of HHG by tuning the CEP shift with peak intensity $1 \times 10^{14}$ W/cm$^2$. For clarity, HHG peaks of the comb structure are connected by a line.
Table 4.1: Effects on the power spectra by varying the CEP shift $\Delta \phi$. $q$ is the harmonic order of the maximum peak for each harmonic and $P(q\omega_c)$ is the corresponding to power spectrum at $\omega = q\omega_c$. The label A indicates $\Delta \phi/2\pi = 0.1$ that shows off-resonance cases, while B indicates the near-resonance cases: $\Delta \phi/2\pi = 0.168295$, 0.20653, and 0.2697 for $1 \times 10^{14}$, $1 \times 10^{15}$, and $2.5 \times 10^{15}$ W/cm$^2$, respectively. The number in brackets indicates the power of 10.

Chapter 5

Generalized Floquet approach for the exploration of multiphoton quantum interference in a superconducting qubit driven by intense ac fields

We present a Floquet treatment of multiphoton phenomena in a strongly driven superconducting flux qubit. The periodically time-dependent Schrödinger equation can be reduced to an equivalent time-independent infinite-dimensional Floquet matrix eigenvalue problem. For resonant or nearly resonant multiphoton transitions, we extend the generalized Van Vleck (GVV) nearly degenerate high-order perturbation theory for the treatment of the Floquet Hamiltonian. The GVV approach allows accurate treatment of ac Stark shift, power broadening, time-dependent and time-averaged transition probability, etc., well beyond the rotating wave approximation. We extend the Floquet and GVV approaches for numerical and analytical studies of the multiphoton resonance
processes and quantum interference phenomena for the superconducting flux qubit system driven by intense ac fields.

5.1 Superconducting flux qubit

Superconducting flux qubit [222] is a promising candidate for quantum computing [4]. When the superconducting flux qubit is driven by an oscillating field, it involves plentiful dynamics of macroscopic quantum states such as Rabi oscillations and coherent control [223, 224, 225]. Recently, Oliver and colleagues experimentally demonstrated multiphoton resonance and quantum interference in a strongly driven flux qubit as an analogue of Mach–Zehnder interferometry [226, 227]. The peaks in the transition probability between two qubit states form fringe patterns around multiphoton resonance positions. This is explained by the phase differences of the qubit states after they are swept by a strong driving field [226]. Since the strongly driven qubit can be modeled by a two-level system interacting with the strong oscillating field, the development of an analytical approach for a time-dependent problem is desirable to explore the rich dynamics of the two-level system. Understanding dynamics of strongly driven two-level systems is important to superconducting approach of quantum computation.

The two-level system interacting with the external field through off-diagonal time-dependent couplings (transverse couplings) has been extensively studied in the framework of the Floquet theory [28, 221, 228]. On the contrary, the qubit that is the two-level system interacting through diagonal couplings (longitudinal couplings) with driving fields has been investigated only within the rotating wave approximation (RWA) [226, 229]. RWA includes only one resonant
term, whereas the generalized Van Vleck (GVV) nearly degenerate perturbation theory [230, 231, 232] includes all leading terms that result in the ac Stark level shift and power broadening of multiphoton resonance positions [220, 228]. Recently, Ashhab et al. [233] have studied the two-level system within RWA and the transfer-matrix approach, and Greenberg [234] and Wilson et al. [235] have studied the qubit using the dressed-state approach. However, to the best of our knowledge, the ac Stark level shift for multiphoton resonance processes which appears beyond RWA has not been considered so far for this qubit system. As to be shown later, the consideration of level shift and power broadening is significant for quantitative exploration of multiphoton quantum interference phenomena in the superconducting qubit. We extend the Floquet theory for a comprehensive investigation of the strongly driven qubit system and provide insightful GVV analytic solutions to better understand multiphoton resonance condition including the level shift and coherent quantum interference patterns.

The superconducting flux qubit discussed here is a compound Josephson junction (CJJ) radio-frequency superconducting quantum interference device (rf SQUID) [236], which consists of a main loop and a CJJ loop subjected to external flux biases $\Phi_x$ and $\Phi_x^{\text{CJJ}}$, respectively, as shown in Fig. 5.1. The Hamiltonian of the CJJ rf SQUID can be approximated by a double-well potential as a function of the total flux threading the main loop. Two logical qubit states are assigned to the opposite circulation direction of persistent currents in the loop. The clockwise current corresponds to $|\alpha\rangle$, while the counterclockwise to $|\beta\rangle$. If the temperature is much less than the small oscillation frequency (i.e., the plasma frequency) at the bottom of the double-well potential, the superconduct-
A positive slope of the dispersion curve corresponds to $|\beta\rangle$ (counterclockwise), while a negative slope to $|\alpha\rangle$ (clockwise). These two states are coupled through the tunneling strength $\Delta$ and show the avoided crossing at $\varepsilon_0 = 0$ as shown in Fig. 5.2. Thus, $\Delta$ is given by the energy separation of two eigenstates of $H_0$ at $\varepsilon_0 = 0$ which are $(|\alpha\rangle - |\beta\rangle) / \sqrt{2}$ and $(|\alpha\rangle + |\beta\rangle) / \sqrt{2}$. Both the persistent current and the tunneling strength are controlling parameters of the qubit states. When the qubit becomes localized in $|\alpha\rangle$ or $|\beta\rangle$, the persistent current generates
a magnetic flux that can be detected by an inductively coupled dc SQUID as described in Ref. [236].

### 5.2 Floquet formulation for the superconducting flux qubit

The generalized Floquet formalisms [28] have been developed and applied to a number of time-dependent problems: from monochromatic to polychromatic [217] and frequency-comb laser fields [54], and from two-level models to realistic atomic and molecular systems [28, 32, 238, 239] and the electron transport of nanoscale systems [240]. It provides a non-perturbative and accurate treatment of the interaction of a quantum system with intense time-dependent fields.

When the superconducting flux qubit is driven by a strong ac field, the time-dependent Hamiltonian [226] is given as

$$H(t) = -\frac{1}{2} \begin{pmatrix} \epsilon(t) & \Delta \\ \Delta & -\epsilon(t) \end{pmatrix},$$

(5.2)
where $\varepsilon(t) = \varepsilon_0 + A \cos \omega t$. Note that for typical superconducting flux qubits the longitudinal coupling is more commonly used than the transverse coupling. $\omega$ is the angular frequency of the driving ac field and $A$ is its amplitude that is parametrized in the energy unit and proportional to ac flux bias [227]. Note that this Hamiltonian generally describes the two-level system interacting through the longitudinal coupling and is directly applicable to other qubit systems. For example, in Cooper-pair box qubits [235] the electrostatic energy and the Josephson coupling energy directly correspond to $\varepsilon_0$ and $\Delta$ in Eq. (5.2), respectively.

The generalized Floquet theory [28] provides an exact formulation of time-periodic problems and a combined picture of the $N$-level system and electromagnetic fields by the use of quasienergy states. According to the Floquet theorem [241], the time-dependent Schrödinger equation with a given time-periodic Hamiltonian,

$$i\hbar \frac{\partial}{\partial t} \psi(t) = H(t)\psi(t),$$

(5.3)

has a solution that can be written as

$$\psi(t) = e^{-iqt/\hbar} \phi(t),$$

(5.4)

where $\phi(t)$ is periodic in time and $q$ is called the quasienergy. When Eq. (5.4) is substituted into Eq. (5.3), we obtain an eigenvalue equation for the quasienergy,

$$\left[ H(t) - i\hbar \frac{\partial}{\partial t} \right] \phi(t) = q\phi(t).$$

(5.5)

The periodically time-dependent problem can be transformed into an equivalent time-independent infinite-dimensional generalized Floquet matrix eigen-
value problem [28, 221]. The temporal part of the Hamiltonian $H(t)$ and the quasi-energy eigenfunction $\phi(t)$ is expanded with the Fourier components of $\omega$,

$$
H(t) = \sum_n H[n] e^{-in\omega t},
$$

(5.6)

$$
\phi(t) = \sum_n \phi[n] e^{-in\omega t},
$$

(5.7)

where $H[n]$ and $\phi[n]$ are spanned by any orthonormal basis set. We can employ the Floquet-state nomenclature [28],

$$
|an\rangle = |\alpha\rangle \otimes |n\rangle,
$$

(5.8)

where $\alpha$ is the system index and $n$ is the Fourier index that runs from $-\infty$ to $\infty$. Note that in the generalized Floquet formalism $\alpha$ can be the $N$-level system index, but for the effective Hamiltonian of Eq. (5.2) it is restricted to the qubit state ($N=2$). Substituting Eqs. (5.6) and (5.7) into Eq. (5.5) and employing Eq. (5.8), we obtain the following time-independent Floquet matrix eigenvalue equation,

$$
\sum_\beta \sum_m \langle an|H_F|\beta m\rangle \langle \beta m|q_{\gamma l}\rangle = q_{\gamma l} \langle an|q_{\gamma l}\rangle,
$$

(5.9)

where $q_{\gamma l}$ is the quasienergy eigenvalue and $|q_{\gamma l}\rangle$ is the corresponding eigenvector, $\langle an|q_{\gamma l}\rangle = \phi^{[n-l]}_{\alpha\gamma}$. Here, $H_F$ is the time-independent Floquet Hamiltonian defined by

$$
\langle an|H_F|\beta m\rangle = H^{[n-m]}_{\alpha\beta} + n\hbar \omega \delta_{\alpha\beta} \delta_{nm}.
$$

(5.10)

For simplicity, we set $\hbar = 1$ hereafter.
The time-dependent Hamiltonian for the superconducting flux qubit in Eq. (5.2) is expanded with the Fourier components of $\omega$,

$$H(t) = H_0 - \frac{A \cos \omega t}{2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} = H_0 - \frac{A(e^{i\omega t} + e^{-i\omega t})}{4} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \quad (5.11)$$

By comparing Eq. (5.6), there are only three non-vanishing Fourier components:

$$H^{[0]} = -\frac{1}{2} \begin{pmatrix} \epsilon_0 & \Delta \\ \Delta & -\epsilon_0 \end{pmatrix}, \quad H^{[+1]} = -\frac{A}{4} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad \text{and} \quad H^{-[1]} = -\frac{A}{4} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad (5.12)$$

where $H^{[n-m]} + n\omega \delta_{nm} I (I: 2 \times 2 \text{ identity matrix})$ forms the $n$th column and the $m$th row of the Floquet blocks.

Here we employ the Floquet-state nomenclature in Eq. (5.8),

$$|\alpha n\rangle = |\alpha\rangle \otimes |n\rangle, \quad (5.13)$$

where $\alpha$ is the system index ($\alpha$ or $\beta$) and $n$ is the Fourier index ($-\infty < n < \infty$). Then we construct the matrix eigenvalue equation,

$$\sum_\beta \sum_m \langle \alpha n | H_F | \beta m \rangle \langle \beta m | q_{\gamma l} \rangle = q_{\gamma l} \langle \alpha n | q_{\gamma l} \rangle, \quad (5.14)$$

where $H_F$ is the time-independent Floquent matrix, $q_{\gamma l}$ is the quasienergy eigenvalue, and $|q_{\gamma l}\rangle$ is the corresponding eigenvector.

The Floquet matrix $H_F$ for the qubit represented by bases of $|\alpha n\rangle$ and $|\beta m\rangle$ according to Eq. (5.10) is given as follows:
\[ H_F = \begin{pmatrix} \ddots & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots \\ -\frac{\epsilon_0}{2} - 2\omega & -\frac{A}{2} & -\frac{A}{4} & 0 & 0 & 0 & 0 \\ -\frac{A}{2} & -\frac{\epsilon_0}{2} - 2\omega & 0 & \frac{A}{4} & 0 & 0 & 0 \\ -\frac{A}{4} & 0 & -\frac{\epsilon_0}{2} - \omega & -\frac{A}{2} & -\frac{A}{2} & 0 & 0 \\ 0 & \frac{A}{4} & -\frac{A}{2} & -\frac{\epsilon_0}{2} - \omega & 0 & \frac{A}{4} & 0 \\ 0 & 0 & -\frac{A}{4} & 0 & -\frac{\epsilon_0}{2} + \omega & -\frac{A}{2} & -\frac{A}{2} \\ 0 & 0 & 0 & \frac{A}{4} & -\frac{A}{2} & -\frac{\epsilon_0}{2} + \omega & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{A}{4} & -\frac{A}{2} & -\frac{\epsilon_0}{2} + 2\omega \end{pmatrix} \]

\begin{align*}
\begin{array}{cccccccc}
|\alpha, -2\rangle & |\beta, -2\rangle & |\alpha, -1\rangle & |\beta, -1\rangle & |\alpha, 0\rangle & |\beta, 0\rangle & |\alpha, +1\rangle & |\beta, +1\rangle & |\alpha, +2\rangle & |\beta, +2\rangle \\
\end{array}
\end{align*}

(5.15)
Eigenvalues of this Floquet matrix are numerically solved by truncating the number of the Floquet blocks. For numerical solutions in Section 5.4, 101 Floquet blocks \((n = -50 \sim 50)\) are included to be sufficiently converged for multiphoton processes. It is worthwhile to note that there has been no approximation made in Eq. (5.15) to solve the time-dependent Hamiltonian of Eq. (5.2). Therefore, Eq. (5.15) can be applied for all parameter regimes.

After solving eigenvectors of the Floquet matrix, the time-averaged transition probability between \(|\alpha\rangle\) and \(|\beta\rangle\) can be computed by

\[
P_{\alpha \rightarrow \beta} = \sum_n \sum_{\gamma l} |\langle \beta n | q_{\gamma l} \rangle \langle q_{\gamma l} | \alpha 0 \rangle|^2,
\]

which is corresponding to the probability of finding the excited state of the qubit in experiment.

### 5.3 Analytic solution of the Floquet matrix for the driven qubit

To solve the Floquet matrix of Eq. (5.15) analytically, we employ the generalized Van Vleck (GVV) nearly degenerate perturbation theory \([230, 231, 232]\). By introducing a perturbation parameter, \(\lambda = -\Delta/2\), the Floquet matrix can be divided into unperturbed and perturbed parts,

\[
H_F = H_0 + \lambda V,
\]

where \(H_0\) has the following matrix structure,
\[ H_0 = \left( \begin{array}{ccc|ccc|ccc|ccc|ccc} \vdots & & & & & & & \vdots \\ -\frac{\epsilon_0}{4} - 2\omega & 0 & -\frac{A}{4} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \alpha, -2 \\\\ 0 & \frac{\epsilon_0}{4} - 2\omega & 0 & \frac{A}{4} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \beta, -2 \\\\ -\frac{A}{4} & 0 & -\frac{\epsilon_0}{2} - \omega & 0 & -\frac{A}{4} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \alpha, -1 \\\\ 0 & \frac{A}{4} & 0 & \frac{\epsilon_0}{2} - \omega & 0 & \frac{A}{4} & 0 & 0 & 0 & 0 & 0 & 0 & \beta, -1 \\\\ \hline \\ 0 & 0 & -\frac{A}{4} & 0 & -\frac{\epsilon_0}{2} & 0 & -\frac{A}{4} & 0 & 0 & 0 & 0 & 0 & \alpha, 0 \\\\ 0 & 0 & 0 & \frac{A}{4} & 0 & \frac{\epsilon_0}{2} & 0 & \frac{A}{4} & 0 & 0 & 0 & 0 & \beta, 0 \\\\ \hline \\ 0 & 0 & 0 & 0 & -\frac{A}{4} & 0 & -\frac{\epsilon_0}{2} + \omega & 0 & -\frac{A}{4} & 0 & 0 & 0 & \alpha, +1 \\\\ 0 & 0 & 0 & 0 & 0 & \frac{A}{4} & 0 & \frac{\epsilon_0}{2} + \omega & 0 & \frac{A}{4} & 0 & 0 & \beta, +1 \\\\ \hline \\ 0 & 0 & 0 & 0 & 0 & 0 & -\frac{A}{4} & 0 & -\frac{\epsilon_0}{2} + 2\omega & 0 & 0 & 0 & \alpha, +2 \\\\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & \frac{A}{4} & 0 & \frac{\epsilon_0}{2} + 2\omega & 0 & 0 & \beta, +2 \\\\ \hline \\ \vdots & & & & & & & \vdots \\\\ \end{array} \right) \]

\[ \Delta \Xi \]

(5.18)
To obtain the eigenstates of $H_0$, Eq. (5.18) can be separated into two segments because all off-diagonals are zero in each $2 \times 2$ block, i.e., $|\alpha\rangle$ and $|\beta\rangle$ are decoupled in $H_0$,

$$
H_0(\alpha \text{ or } \beta) = \begin{pmatrix}
\vdots & \\
 & b-2\omega & a & 0 & 0 & 0 \\
 & a & b-\omega & a & 0 & 0 \\
 & 0 & a & b & a & 0 & \cdots \\
 & 0 & 0 & a & b+\omega & a \\
 & 0 & 0 & 0 & a & b+2\omega & \\
 & \vdots & & & & & \ddots
\end{pmatrix}, \quad (5.19)
$$

where $b = -\varepsilon_0/2$ and $a = -A/4$ for the state of $|\alpha\rangle$, and $b = +\varepsilon_0/2$ and $a = +A/4$ for $|\beta\rangle$. Eigenvalues and eigenvectors of Eq. (5.19) can be analytically solved in terms of Bessel functions $J_k(x)$ as follows.

The infinite-dimensional tridiagonal matrix in Eq. (5.19) can be considered as a Floquet matrix transformed from a function $h(t) = b + 2a \cos \omega t$ with Fourier bases of $|k\rangle$ ($k$ is an integer), where $a$ and $b$ are given numbers. After an inverse transformation, the original equation to be solved is the following eigenvalue problem,

$$
\left[ h(t) - i \frac{\partial}{\partial t} \right] \phi(t) = \lambda \phi(t). \quad (5.20)
$$

A trivial solution is $\lambda = b$. Its eigenfunction is given by a Fourier expansion with Bessel functions [242],

$$
\phi(t) = e^{-i \frac{2a}{\omega} \sin \omega t} = \sum_{k=-\infty}^{\infty} J_k \left( -\frac{2a}{\omega} \right) e^{ik\omega t}. \quad (5.21)
$$
For eigenvalues of \( \lambda_n = b + n\omega \) \((n\) is an integer), \( \phi_n(t) \) is solved as

\[
\phi_n(t) = e^{i\omega t}e^{-i\frac{2a}{\omega}\sin\omega t} = \sum_{k=-\infty}^{\infty} J_k \left( -\frac{2a}{\omega} \right) e^{i(n+k)\omega t} = \sum_{k=-\infty}^{\infty} J_{k-n} \left( -\frac{2a}{\omega} \right) e^{i\omega t}.
\]

(5.22)

To summarize, eigenvalues and eigenvectors of Eq. (5.19) are

**Eigenvalues:** \( b + n\omega \) \((n\) any integer), \( (5.23a) \)

**Eigenvectors:** \( \phi_n = \sum_{k=-\infty}^{\infty} J_{k-n} \left( -\frac{2a}{\omega} \right) |k\rangle \). \( (5.23b) \)

Therefore, the eigenstates of \( H_0 \) in Eq. (5.18) are represented as follows,

\[
|\alpha', n\rangle = \sum_{k=-\infty}^{\infty} J_{k-n} \left( \frac{A}{2\omega} \right) |\alpha k\rangle, \quad (5.24a)
\]

\[
|\beta', m\rangle = \sum_{k=-\infty}^{\infty} J_{k-m} \left( -\frac{A}{2\omega} \right) |\beta k\rangle. \quad (5.24b)
\]

Since the GVV method requires the eigenstates for the unperturbed Hamiltonian, the Floquet matrix \( H_F \) in Eq. (5.15) needs to be rewritten in terms of the bases of \( |\alpha', n\rangle \) and \( |\beta', m\rangle \). Let \( z = A/2\omega \) and \( J_k' = J_k(A/\omega) \). From \( \langle ak|H_F|\beta l\rangle = -\frac{2}{\omega}\delta_{kl} \) in Eq. (5.15) and the addition theorem for Bessel function \( J_n(y+z) = \sum_m J_m(y)J_{n-m}(z) \) for any integer \( n \) \( [242] \), one can obtain

\[
\langle \alpha', n|H_F|\beta', m\rangle = \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} J_{k-n}(z)J_{l-m}(-z)\langle ak|H_F|\beta l\rangle
\]

\[
= -\frac{\Delta}{2} \sum_{k=-\infty}^{\infty} J_{k-n}(z)J_{k+m}(z) = -\frac{\Delta}{2} J_{m-n}(2z), \quad (5.25)
\]

\[
\langle \beta', m|H_F|\alpha', n\rangle = \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} J_{k-n}(-z)J_{l-m}(z)\langle \beta k|H_F|\alpha l\rangle
\]

\[
= -\frac{\Delta}{2} \sum_{k=-\infty}^{\infty} J_{-k+n}(z)J_{k-m}(z) = -\frac{\Delta}{2} J_{n-m}(2z). \quad (5.26)
\]
From \( \langle ak|H_F|al \rangle = \left( -\frac{\varepsilon_0}{2} + k\omega \right) \delta_{kl} - \frac{A}{4} \{ \delta_{k,l+1} + \delta_{k,l-1} \} \) in Eq. (5.15), a recursive relation for Bessel function \( J_{n-1}(z) + J_{n+1}(z) = \frac{2n}{z} J_n(z) \) \([242]\), and summation of \( \sum_m J_m(z) J_{m-n}(z) = \sum_m J_m(z) J_{-m+n}(-z) = J_n(0) = \delta_{n0} \) for any integer \( n \), one can obtain

\[
\langle \alpha', n|H_F|\alpha', m \rangle = \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} J_{k-n}(z) J_{l-m}(z) \langle ak|H_F|al \rangle \\
= \sum_{k=-\infty}^{\infty} J_{k-n}(z) \left[ \left( -\frac{\varepsilon_0}{2} + k\omega \right) J_{k-m}(z) - \frac{A}{4} \{ J_{k-m-1}(z) + J_{k-m+1}(z) \} \right] \\
= \sum_{k=-\infty}^{\infty} J_{k-n}(z) \left[ -\frac{\varepsilon_0}{2} + k\omega - (k-m)\omega \right] J_{k-m}(z) \\
= \left( -\frac{\varepsilon_0}{2} + n\omega \right) \sum_{k=-\infty}^{\infty} J_{k-n}(z) J_{k-m}(z) \\
= \left( -\frac{\varepsilon_0}{2} + n\omega \right) \delta_{nm}. \tag{5.27}
\]

Likewise, from \( \langle bk|H_F|bl \rangle = \left( -\frac{\varepsilon_0}{2} + k\omega \right) \delta_{kl} + \frac{A}{4} \{ \delta_{k,l+1} + \delta_{k,l-1} \}, \)

\[
\langle \beta', n|H_F|\beta', m \rangle = \left( \frac{\varepsilon_0}{2} + n\omega \right) \delta_{nm}. \tag{5.28}
\]

Therefore, with equations from (5.25) to (5.28) the Floquet matrix is now represented by the bases of \(|\alpha', n\rangle\) and \(|\beta', m\rangle\) as follows:
\[ H'_F = \begin{pmatrix} \cdots & \cdots \\ -\frac{\alpha}{2} - 2\omega & -\frac{\Delta}{2} J'_0 & 0 & -\frac{\Delta}{2} J'_1 & 0 & -\frac{\Delta}{2} J'_2 & 0 & -\frac{\Delta}{2} J'_3 & 0 & -\frac{\Delta}{2} J'_4 & \cdots \\ -\frac{\Delta}{2} J'_0 & \frac{\epsilon_0}{2} - 2\omega & -\frac{\Delta}{2} J'_{-1} & 0 & -\frac{\Delta}{2} J'_{-2} & 0 & -\frac{\Delta}{2} J'_{-3} & 0 & -\frac{\Delta}{2} J'_{-4} & 0 & \cdots \\ 0 & -\frac{\Delta}{2} J'_{-1} & -\frac{\epsilon_0}{2} - \omega & -\frac{\Delta}{2} J'_0 & 0 & -\frac{\Delta}{2} J'_1 & 0 & -\frac{\Delta}{2} J'_2 & 0 & -\frac{\Delta}{2} J'_3 & \cdots \\ -\frac{\Delta}{2} J'_1 & 0 & -\frac{\Delta}{2} J'_0 & \frac{\epsilon_0}{2} - \omega & -\frac{\Delta}{2} J'_{-1} & 0 & -\frac{\Delta}{2} J'_{-2} & 0 & -\frac{\Delta}{2} J'_{-3} & 0 & \cdots \\ 0 & -\frac{\Delta}{2} J'_{-2} & 0 & -\frac{\Delta}{2} J'_{-1} & -\frac{\epsilon_0}{2} - \omega & -\frac{\Delta}{2} J'_0 & 0 & -\frac{\Delta}{2} J'_1 & 0 & -\frac{\Delta}{2} J'_2 & \cdots \\ -\frac{\Delta}{2} J'_2 & 0 & -\frac{\Delta}{2} J'_1 & 0 & -\frac{\Delta}{2} J'_0 & \frac{\epsilon_0}{2} - \omega & -\frac{\Delta}{2} J'_{-1} & 0 & -\frac{\Delta}{2} J'_{-2} & 0 & \cdots \\ 0 & -\frac{\Delta}{2} J'_{-3} & 0 & -\frac{\Delta}{2} J'_{-2} & 0 & -\frac{\Delta}{2} J'_{-1} & -\frac{\epsilon_0}{2} + \omega & -\frac{\Delta}{2} J'_0 & 0 & -\frac{\Delta}{2} J'_1 & \cdots \\ -\frac{\Delta}{2} J'_3 & 0 & -\frac{\Delta}{2} J'_2 & 0 & -\frac{\Delta}{2} J'_1 & 0 & -\frac{\Delta}{2} J'_0 & \frac{\epsilon_0}{2} + \omega & -\frac{\Delta}{2} J'_{-1} & 0 & \cdots \\ 0 & -\frac{\Delta}{2} J'_{-4} & 0 & -\frac{\Delta}{2} J'_{-3} & 0 & -\frac{\Delta}{2} J'_{-2} & 0 & -\frac{\Delta}{2} J'_{-1} & -\frac{\epsilon_0}{2} + 2\omega & -\frac{\Delta}{2} J'_0 & \cdots \\ -\frac{\Delta}{2} J'_4 & 0 & -\frac{\Delta}{2} J'_3 & 0 & -\frac{\Delta}{2} J'_2 & 0 & -\frac{\Delta}{2} J'_1 & 0 & -\frac{\Delta}{2} J'_0 & \frac{\epsilon_0}{2} + 2\omega & \cdots \\ \cdots & \cdots \end{pmatrix} \]

\[ \begin{array}{cccccccc} \uparrow & \uparrow & \uparrow & \uparrow & \uparrow & \uparrow & \uparrow & \uparrow & \uparrow & \uparrow \\ |\alpha', -2\rangle & |\beta', -2\rangle & |\alpha', -1\rangle & |\beta', -1\rangle & |\alpha', 0\rangle & |\beta', 0\rangle & |\alpha', +1\rangle & |\beta', +1\rangle & |\alpha', +2\rangle & |\beta', +2\rangle \end{array} \]

(5.29)
From the matrix structure of Eq. (5.29), one can see that $|\alpha', 0\rangle$ is coupled to $|\beta', -n\rangle$ throughout an off-diagonal term of $-\frac{\Delta}{2}J_{-n}$. When the Floquet states $|\alpha', 0\rangle$ and $|\beta', -n\rangle$ are nearly degenerate, namely, $-\epsilon_0/2 \approx \epsilon_0/2 - n\omega$, Eq. (5.29) is reduced to a $2 \times 2$ matrix by neglecting all other coupling terms except the one between $|\alpha', 0\rangle$ and $|\beta', -n\rangle$,

$$H_{\text{RWA}} = \begin{pmatrix} -\frac{\epsilon_0}{2} & -\frac{\Delta}{2}J_{-n} \\ -\frac{\Delta}{2}J_{-n} & \frac{\epsilon_0}{2} - n\omega \end{pmatrix}. \tag{5.30}$$

This is equivalent to the rotating wave approximation (RWA), whose form is identical to previous works used for the superconducting qubit subject to the longitudinal coupling [226, 229, 233]. Note that this RWA is different from conventional one subject to the transverse coupling, where RWA breaks down in the strong field [228].

To go beyond RWA, we extend the GVV method allowing the reduction of the infinite-dimensional $H'_F$ into a $2 \times 2$ effective Hamiltonian which includes all $n$-photon coupling channels. With the perturbation parameter $\lambda = -\Delta/2$, the Floquet matrix of Eq. (5.29) is divided into

$$H'_F = H'_0 + \lambda V', \tag{5.31}$$
where

$$H_0' = \begin{pmatrix}
\ddots & \vdots & \vdots & \vdots \\
-\frac{\varepsilon_0}{2} - \omega & 0 & 0 & 0 \\
0 & \frac{\varepsilon_0}{2} - \omega & 0 & 0 \\
0 & 0 & -\frac{\varepsilon_0}{2} & 0 \\
0 & 0 & 0 & \frac{\varepsilon_0}{2} \\
0 & 0 & 0 & -\frac{\varepsilon_0}{2} + \omega & 0 \\
0 & 0 & 0 & 0 & \frac{\varepsilon_0}{2} + \omega \\
\vdots & \vdots & \vdots & \vdots & \ddots \\
\end{pmatrix}, \quad (5.32)$$

and

$$V' = \begin{pmatrix}
\ddots & \vdots & \vdots & \vdots \\
0 & J'_0 & 0 & J'_1 & 0 & J'_2 \\
J'_0 & 0 & J'_{-1} & 0 & J'_{-2} & 0 \\
0 & J'_{-1} & 0 & J'_0 & 0 & J'_1 \\
J'_1 & 0 & J'_0 & 0 & J'_{-1} & 0 \\
0 & J'_{-2} & 0 & J'_{-1} & 0 & J'_0 \\
J'_2 & 0 & J'_1 & 0 & J'_0 & \ddots \\
\vdots & \vdots & \vdots & \vdots & \ddots & \ddots \\
\end{pmatrix}. \quad (5.33)$$

The aim is to reduce the infinite-dimensional Floquet matrix of Eq. (5.29) into the $2 \times 2$ matrix. According to the nearly degenerate perturbation formalism in the GVV method \cite{230, 231, 232}, the $2 \times 2$ matrix $h$ and its eigenstate solution $\phi$ can be expanded in powers of $\lambda$,

$$h = \sum_{m=0}^{\infty} \lambda^m h^{(m)}, \quad (5.34)$$
\[ \phi = \sum_{m=0}^{\infty} \lambda^m \phi^{(m)}. \] (5.35)

For \( n \)-photon resonance, the Floquet states \( |\alpha', 0\rangle \) and \( |\beta', -n\rangle \) are nearly degenerate. Thus, the zeroth-order \( \phi^{(0)} = (\phi_-^{(0)} \phi_+^{(0)})^T \) is given by

\[ \phi_-^{(0)} = |\alpha', 0\rangle \quad \text{and} \quad \phi_+^{(0)} = |\beta', -n\rangle. \] (5.36)

The zeroth-order \( h^{(0)} \) represented by \( \phi_-^{(0)} \) and \( \phi_+^{(0)} \) is given by

\[
h^{(0)} = \begin{pmatrix} -\frac{\varepsilon_0}{2} & 0 \\ 0 & \frac{\varepsilon_0}{2} - n\omega \end{pmatrix}, \] (5.37)

where two eigenstates are nearly degenerate, i.e., \( \varepsilon_0 \approx n\omega \). Following the GVV method, a few high-order terms can be computed as follows:

\[ \phi_-^{(1)} = \sum_{k=-\infty}^{\infty} \frac{-J'_k}{\varepsilon_0 + k\omega} |\beta', k\rangle, \quad \text{and} \quad \phi_+^{(1)} = \sum_{k=-\infty}^{\infty} \frac{J'_k}{\varepsilon_0 + k\omega} |\alpha', -n - k\rangle, \] (5.38)

\[
h^{(1)} = \langle \phi^{(0)} | V' | \phi^{(0)} \rangle = J'_{-n} \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \] (5.39)

\[
h^{(2)} = \langle \phi^{(0)} | V' | \phi^{(1)} \rangle - h^{(1)} \langle \phi^{(0)} | \phi^{(1)} \rangle = \sum_{k=-\infty}^{\infty} \frac{J'^2_k}{\varepsilon_0 + k\omega} \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \] (5.40)

\[
h^{(3)} = \langle \phi^{(1)} | V' | \phi^{(1)} \rangle - \langle \phi^{(1)} | \phi^{(1)} \rangle h^{(1)}
\]

\[
= -\sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} \sum_{k'=-\infty}^{\infty} \frac{J'^2_k J'^l_{k+l+n}}{\varepsilon_0 + k\omega \varepsilon_0 + l\omega} + \frac{J'^2_k J'_{-n}}{(\varepsilon_0 + k\omega)^2} \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}. \] (5.41)
After adding these higher-order terms, one can obtain the $2 \times 2$ matrix as,

$$
H_{\text{GVV}} = \begin{pmatrix}
-\frac{\varepsilon_0}{2} + \delta & u \\
u & \frac{\varepsilon_0}{2} - \delta - n\omega
\end{pmatrix},
$$

where $\delta$ is the ac Stark level shift and $u$ is the non-vanishing off-diagonal term which is related to the power broadening of the transition probability peaks,

$$
u = j'_{-n}\lambda - \sum_{k=-\infty}^{\infty} \sum_{l \neq -n} \left[ \frac{j'_{k}j'_{k+l+n}}{(\varepsilon_0 + k\omega)(\varepsilon_0 + l\omega)} + \frac{j'^2_{k}j'_{-n}}{(\varepsilon_0 + k\omega)^2} \right] \lambda^3 + O(\lambda^5),
$$

$$
\delta = -\sum_{k=-\infty}^{\infty} \frac{j'^2_{k}}{\varepsilon_0 + k\omega} \lambda^2 + O(\lambda^4).
$$

The leading term of $\nu$ comes from the first-order in Eq. (5.39), and the leading term of $\lambda$ is from the second-order in Eq. (5.40). In other words, most of dominant terms involving all multiphoton resonance processes are taken into account within the second-order perturbation of $\lambda$, in contrast to the conventional transverse coupling case that requires the $(2n + 1)$th-order perturbation to obtain the non-vanishing terms for $n$-photon process [228]. If one considers the first-order term only, $H_{\text{GVV}}$ is reduced to $H_{\text{RWA}}$. Note that Eqs. (5.42)–(5.44) are valid regardless of the strong or weak driving field amplitude $A$.

The effective Hamiltonian of Eq. (5.42) has the standard form for the two-level system in an oscillating field beyond RWA [28, 220, 221, 228]. Eigenvalues of Eq. (5.42) are given by

$$
q_{\pm} = -\frac{n\omega}{2} \pm p,
$$

145
where
\[ p^2 = \frac{(n\omega - \varepsilon_0 + 2\delta)^2}{4} + u^2. \]  

(5.46)

The \( n \)-photon time-dependent transition probability from \( |\alpha\rangle \) to \( |\beta\rangle \) is obtained by
\[ P_{\alpha \rightarrow \beta}^{(n)}(t) = \frac{u^2}{p^2} \sin^2(pt), \]

(5.47)

and the \( n \)-photon time-averaged transition probability is obtained by
\[ \bar{P}_{\alpha \rightarrow \beta}^{(n)} = \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T P_{\alpha \rightarrow \beta}^{(n)}(t) dt = \frac{1}{2} \cdot \frac{u^2}{ u^2 + (n\omega - \varepsilon_0 + 2\delta)^2/4}. \]

(5.48)

With the first-order term only (RWA limit), it yields to
\[ P_{\alpha \rightarrow \beta}^{(n)} = \frac{1}{2} \cdot \frac{(\Delta J_n')^2}{(\Delta J_n')^2 + (n\omega - \varepsilon_0)^2}. \]

(5.49)

since \( J_{-n}(x) = (-1)^n J_n(x) \). This RWA result is identical with previous formulation in Ref. [226]. Note that the first-order expression does not contain the level shift term.

Let us now investigate the behavior of the level shift \( \delta \) in the weak and strong driving field regimes. The level shift is particularly important in qubit calibration because it determines the accurate positions of resonance peaks. From the second-order GVV in Eq. (5.44), \( \delta \) is proportional to \( \Delta^2 \) and given by the series with the Bessel function involving \( A \) as its argument. For small arguments \( x \ll 1 \), the Bessel function has the following asymptotic form,
\[ J_k(x) \approx \frac{1}{k!} \left( \frac{x}{2} \right)^k \quad (k \geq 0), \]

(5.50)
where \( x = A/\omega \). Thus, in the weak-field regime, \( J'_0 \) is dominant over \( J'_k (k \neq 0) \). When only \( J'_0 \) is included in the sum of Eq. (5.44), \( \delta \) is approximated as

\[
\delta = -\frac{\Delta^2}{4\varepsilon_0} + O(A^2, \Delta^4) \quad (n \geq 1).
\]  

(5.51)

For non-photon-assisted process \( (n = 0) \), there is no \( \Delta^2 \) term in \( \delta \), i.e., \( \delta \approx 0 \) because \( J'_0 \) is excluded in the sum of Eq. (5.44). If we approximate \( \delta \) up to \( O(A^4) \), \( J'_0 (\approx 1 - A^2/4\omega^2) \) and \( J'_\pm 1 (\approx \pm A/2\omega) \) can be included in the sum of Eq. (5.44), which yields to

\[
\delta = -\frac{A^2\Delta^2\varepsilon_0}{8\omega^2(\varepsilon_0^2 - \omega^2)} + O(A^4, \Delta^4) \quad (n = 0) \quad (5.52a)
\]

\[
= -\frac{\Delta^2}{4\varepsilon_0} + \frac{A^2\Delta^2(\varepsilon_0 + 2\omega)}{16\omega^2\varepsilon_0(\varepsilon_0 + \omega)} + O(A^4, \Delta^4) \quad (n = 1) \quad (5.52b)
\]

\[
= -\frac{\Delta^2}{4\varepsilon_0} - \frac{\Delta^2 A^2}{8\varepsilon_0(\varepsilon_0^2 - \omega^2)} + O(A^4, \Delta^4). \quad (n \geq 2) \quad (5.52c)
\]

On the other hand, for large arguments \( (x \to \infty) \), the Bessel function asymptotically becomes

\[
J_k(x) \approx \sqrt{\frac{2}{\pi x}} \cos \left( x - \frac{k\pi}{2} - \frac{\pi}{4} \right),
\]  

(5.53)

and then \( J^2_k \) is approximated as

\[
J^2_k \approx \frac{2\omega}{\pi A} \cos^2 \left( \frac{A}{\omega} - \frac{k\pi}{2} - \frac{\pi}{4} \right) = \frac{\omega}{\pi A} \left\{ 1 + \cos \left( \frac{2A}{\omega} - k\pi - \frac{\pi}{2} \right) \right\}
\]

\[
= \frac{\omega}{\pi A} \left\{ 1 + (-1)^k \sin \left( \frac{2A}{\omega} \right) \right\}. \quad (5.54)
\]
Figure 5.3: Plots of the level shift $\delta$ as a function of the field amplitude $A$.

Thus it yields to $J^2_k \approx J^2_{-k}$. Using this asymptotic expression as well as $\varepsilon_0 \approx n\omega$, $\delta$ in the strong-field regime becomes zero as shown below:

$$
\delta \approx \frac{\Delta^2}{4} \sum_{k=-\infty}^{\infty} \frac{J^2_k}{(n+k)\omega} = -\frac{\Delta^2}{4} \sum_{k=-\infty}^{\infty} \frac{J^2_{k-n}}{k\omega}
$$

$$
= -\frac{\Delta^2}{4} \sum_{k=1}^{\infty} \left[ \frac{J^2_{k-n}}{k\omega} - \frac{J^2_{-k-n}}{k\omega} \right] \approx 0. \quad (5.55)
$$

This is somewhat surprising because the level shift presumably increases as the field amplitude increases like classical examples of the two-level system [28, 32, 221, 228]. For this superconducting qubit system, however, longitudinal terms driven by the strong ac field show different behavior of the level shift. The two harmonic series with the Bessel functions in Eq. (5.55) are diverged separately but canceled by each other because $J^2_{k-n} \approx J^2_{-k-n}$ for all $k$. Therefore, the level shift asymptotically diminishes in the strong field regime. However, $\delta$ does not monotonously decrease because of the summation with the Bessel functions.
in Eq. (5.44). Figure 5.3 shows the change of $\delta$, numerically computed from Eq. (5.44), as a function of the field amplitude $A$ for a few $n$-photon cases. Due to this level shift $\delta$, the multiphoton resonance condition is not $\varepsilon_0 = n\omega$ as derived from RWA, but shifted to

$$\varepsilon_0 - 2\delta = n\omega \quad (n \geq 1).$$

To summarize, the level shift $\delta$ appears more vivid in the weak-field regime. Note that the shift $\delta$ is most prominent when the number of photons involved is small ($n \gtrsim 1$).

### 5.4 Multiphoton resonance process and quantum interference

Figure 5.4 shows the quasienergies and corresponding time-averaged transition probabilities as a function of $\varepsilon_0$ with fixed parameters of $\Delta/\omega = 0.5$ and $A/\omega = 5.0$, computed by solving Eq. (5.15). The solid red lines indicate lower Floquet states and dashed blue lines indicate upper Floquet states. Due to the periodicity of the quasienergy, the quasienergy plot has repeating structure by $\omega$ with the avoided crossings between the lower and upper Floquet states in the vicinity of $\varepsilon_0 \approx n\omega$ ($n$ is a positive integer). At the avoided crossings, the lower and upper Floquet states are strongly mixed and resonance transitions between $|\alpha\rangle$ and $|\beta\rangle$ occur, as shown in the plot of time-averaged transition probability. Also $\varepsilon_0 \approx n\omega$ indicates that these transitions are multiphoton resonance processes.

To compare the numerical and analytic results, we present the transition probability plots as a function of $\varepsilon_0$ in Fig. 5.5, computed by a numerical solu-
Figure 5.4: Plots of quasienergies and transition probabilities as a function of $\varepsilon_0$. $\Delta/\omega = 0.5$ and $A/\omega = 5.0$ are used.
tion of the full matrix of Eq. (5.15) and analytic solutions of the $2 \times 2$ matrices of Eqs. (5.30) and (5.42). Figure 5.5(a) shows the weak-field case of $A/\omega=0.5$ and Fig. 5.5(b) the strong-field case of $A/\omega=10.0$. $\Delta/\omega=0.5$ is used for both cases. The solid red line indicates the numerical solution by solving a $202 \times 202$ Floquet matrix. The dotted green line is used for the RWA solution, and the dashed blue line for the second-order GVV solution. The third-order GVV result is not shown because it is almost the same as the second-order one in this regime. The analytic GVV expression shows very good agreement with the numerical results near $n$-photon resonance regions, whereas the RWA results show large deviations in the weak-field case in Fig. 5.5(a). The time-averaged transition probability hits the maximum value of $\frac{1}{2}$ near $\epsilon_0 \approx n\omega$. Note that in Fig. 5.5(a) those resonance positions of the numerical and GVV solutions are ac Stark shifted due to the level shift $\delta$ in the weak-field regime. As $\epsilon_0$ increases, this shift becomes smaller according to the dominant terms in Eq. (5.52). Since the RWA method does not include the level shift, the dotted green line remains unshifted. On the other hand, in the strong-field case of Fig. 5.5(b), the level shift diminishes and all lines coincide near the multiphoton resonances.

To reveal the dependence of the ac Stark shift upon the field amplitude, Fig. 5.6 plots quasienergies as a function of $A$. $\epsilon_0/\omega=4.9$ and $\Delta/\omega=0.5$ are fixed. For clarity, Fig. 5.6 shows the behavior of the lower quasienergies only. The GVV results (dashed blue line) coincide with the numerical results (solid red line). In contrast, quasienergies computed by the RWA method (dotted green line) deviates from the numerical results in the weak $A$ region and this deviation decreases as $A$ increases. Oscillating patterns as a function of $A$ are mainly due to $|u|$, i.e., the shape of the Bessel function. From Eqs. (5.45) and (5.46), $q$
Figure 5.5: Comparison for numerical results and analytic RWA and GVV results by the transition probability plots as a function of $\varepsilon_0$. $\Delta/\omega = 0.5$ is used.
Figure 5.6: Comparison for numerical results and analytic RWA and GVV results by the quasienergy plots as a function of $A$. $\Delta/\omega = 0.5$ and $\varepsilon_0/\omega = 4.9$ are used.

mainly involves $|J_n(A/\omega)|$ when $\varepsilon_0 - 2\delta \approx n\omega$. For example, in Fig. 5.6, the oscillating patterns follow $|J_5(A/\omega)|$ because $\varepsilon_0/\omega \approx 5$.

In the transition probability plot of Fig. 5.4, one can see that the width of the peaks varies non-monotonically as $\varepsilon_0$ (i.e., $n$) increases. In fact, these patterns also depend on $A$. These widths are correlated with the difference between the lower and upper states at the avoided crossings in the quasienergy plot. Figures 5.7(a)–(c) show contour maps of the transition probability computed by Eq. (5.16) as a function of $A$ and $\varepsilon_0$ with $\Delta/\omega=0.1$, 0.5, and 1.0, respectively. Multiphoton resonance processes occur near integer numbers closest to $\varepsilon_0/\omega$ indicated as bright yellow fringes in the plot. Figure 5.7(a) with relatively small $\Delta$ agrees well with previous experimental and theoretical results for the superconducting flux qubit [226]. In Figs. 5.7(b) and (c) with large $\Delta$, however, it is clearly shown that the level shift alters multiphoton resonance positions especially in the regime of small $\varepsilon_0$ and weak $A$. Also for all figures resonance tran-
ositions are suppressed at certain positions of \( A \), which is a phenomenon known as the coherent destruction of tunneling [240, 243]. These positions can be determined by the roots of the Bessel function of order of \( n \) that is the nearest integer to \( \varepsilon_0/\omega \) [226, 233]. From the analytic expression of the time-averaged transition probability in Eq. (5.48), we can easily confirm that \( \bar{P}^{(n)}_{\alpha \rightarrow \beta} \rightarrow 0 \) as \( u \rightarrow 0 \). When \( J_n(A/\omega) = 0 \), the first-order of \( \Delta \) in \( u \) in Eq. (5.43) disappears and \( u \) is proportional to \( \Delta^3 \). Thus, the width of the time-averaged transition probability becomes very narrow near the roots of the Bessel function, \( J_n(A/\omega) \), which depends on the number of photons \( n(\approx \varepsilon_0/\omega) \) and the amplitude \( A \).
Figure 5.7: Multiphoton quantum interference fringe patterns of the transition probability in the superconducting qubit driven by intense ac fields as a function of $A$ and $\varepsilon_0$ with different values of $\Delta$. (a) $\Delta/\omega = 0.1$, (b) $\Delta/\omega = 0.5$, and (c) $\Delta/\omega = 1.0$. 
Chapter 6

Conclusion

We introduce the Voronoi-cell finite difference (VFD) method for accurate electronic structure calculations for the first time. Based on the Voronoi diagram and natural neighboring relations, the method provides simple expressions for the discrete Laplacian and gradient operators on unstructured grids. As one of unstructured grid distributions, we introduce highly adaptive multicenter molecular grids combining spherical atomic grids centered at nuclear positions. With the VFD method augmented by multicenter molecular grids, the Schrödinger equation for one-electron systems is solved for accuracy assessment, showing systematic improvement by increasing the number of grids. Then VFD is applied to the density-functional calculations for many-electron polyatomic molecules within good precision in comparison with other calculations. Also we propose the high-order VFD scheme that involves further natural neighboring grid points to improve accuracy and efficiency even better.

Next we develop the new time-dependent Voronoi-cell finite difference (TD-VFD) method to investigate strong-field phenomena of polyatomic molecules in intense ultrashort laser fields, combined with the efficient and accurate time-propagation method of the split-operator technique in the energy representa-
tion. The method is applied to solve the self-interaction-free time-dependent density-functional theory equations for strong-field electronic dynamics including all spin-orbitals and continuum states. We present detailed studies of multiphoton ionization (MPI) of $\text{N}_2$, $\text{H}_2\text{O}$, and $\text{CO}_2$ in intense ultrashort laser fields with arbitrary orientation, including electron correlation and multielectron responses. Our results show that the orientation dependence of MPI is determined by the symmetries and dynamics of multiple orbitals. For $\text{N}_2$, the orientation dependent pattern of MPI is reflected by contributions from HOMO and HOMO$-1$. For $\text{H}_2\text{O}$, the contribution from HOMO$-1$ dominates the overall orientation dependent pattern of MPI when the laser field polarization is varied in a specific direction. For $\text{CO}_2$, the maximum peak of MPI is predicted to be at $40^\circ$ in good agreement with recent experiments, whereas other theoretical models fail to predict the same pattern. The photoelectron angular distribution of $\text{CO}_2$ reveals the delicate relation between the orientation dependence and the molecular orbital symmetry. These features emphasize the importance of multiple orbital contributions to the MPI processes, and enable us to selectively probe individual orbitals in strong-field electronic dynamics. Also we perform high-order harmonic generation (HHG) calculations of $\text{CO}_2$ with arbitrary orientation. Our results show that HHG of $\text{CO}_2$ has the particular orientation dependence influenced by the orientation dependence in the ionization process and the two-center interference in the recombination process.

For the frequency-comb laser, we show that a train of an infinite number of short laser pulses generates spectral combs in the frequency domain, which can be exactly expressed in terms of the main frequency and the repetition frequency. The many-mode Floquet theory utilizing those two frequencies is extended to accurately solve the interaction between the quantum system and
frequency-comb laser. We found that there are simultaneous multiphoton resonance processes between the system and comb laser, and that they can be optimally controlled by tuning the pulse-to-pulse CEP shift. HHG driven by intense frequency-comb laser fields has the comb structure with the same repetition frequency and a different offset for each harmonic. Moreover, HHG can be dramatically enhanced by tuning the CEP shift due to simultaneous multiphoton resonance processes among all the comb frequencies.

Next, we extend the generalized Floquet theory to investigate the superconducting flux qubit driven by a strong ac field. The numerical and analytic solutions of the generalized Floquet formalism are applied to explain multiphoton resonance processes between the qubit and the driving ac field. We compare two analytic solutions: the rotating wave approximation (RWA) and the generalized Van Vleck (GVV) nearly degenerate perturbation theory. It is shown that the GVV approach accurately includes the ac Stark level shift which is completely absent within RWA. The level shifts in resonance positions are significant when the tunnel splitting is large, the field is weak, and a small number of photons are involved. The quasienergy and the time-averaged transition probability from Floquet calculations are plotted showing multiphoton resonance transitions at the avoided crossings. From the transition probability plot as a function of the field amplitude and the detuning energy, we observe the Bessel function-like fringe patterns including the level shift. The general method described here provides a unified theoretical treatment covering a wide range of parameter space. Applications of the Floquet theory to various superconducting qubits lead us to a better understanding of the results of spectroscopy measurement and the dynamics of ac driven qubits which are important to more accurate characterization of and performance improvement of the qubits.
The theoretical and computational methods proposed in this dissertation provide generalized tools to investigate strong-field multiphoton processes. For future works, they can be extended to explore new frontiers of attosecond science, such as molecular attosecond x-ray spectroscopy, attosecond probing and controlling of electron motions in atoms, molecules, and chemical reactions. Also the proposed VFD method on multicenter molecular grids can be employed for advanced quantum chemistry calculations, for examples, basis-set-free Hartree–Fock (HF) and post-HF methods, and grid-based linear-scaling DFT calculations. Since the Voronoi diagram is intrinsically expressed in the multi-dimensional space, it may be possible to extend VFD for a fully ab initio method in 3N-dimensional for N particles, combined with improved high-order scheme. Finally, two approaches explored in this dissertation, VFD and Floquet methods, which have been separately applied for spatial and temporal treatments, can be unified for high-precision atomic and molecular physics.
